1 **Executive Summary**

2
3 This Advisory responds to a request from the EPA Office of Air and Radiation for EPA's
4 Science Advisory Board (SAB) to review and comment on EPA's *Accounting Framework for*
5 *Biogenic CO₂ Emissions from Stationary Sources (Framework, September 2011)*. The
6 *Framework* considers the scientific and technical issues associated with accounting for emissions
7 of biogenic carbon dioxide (CO₂) from stationary sources and develops a framework to adjust the
8 stack emissions from stationary sources using bioenergy based on the induced changes in carbon
9 stocks on land (in soils, plants and forests). To conduct the review, the SAB Staff Office formed
10 the Biogenic Carbon Emissions Panel with experts in forestry, agriculture, greenhouse gas
11 measurement and inventories, land use economics, ecology, climate change and engineering.
12

13 The SAB Biogenic Carbon Emissions Panel was asked to review and comment on
14 (1) EPA's characterization of the science and technical issues relevant to accounting for biogenic
15 CO₂ emissions from stationary sources; (2) EPA's framework, overall approach, and methodological
16 choices for accounting for these emissions; and (3) options for improving upon the framework for
17 accounting for biogenic CO₂ emissions. In the context of EPA's *Framework*, the term "biogenic
18 carbon emissions" refers to emissions of CO₂ from a stationary source directly resulting from the
19 combustion or decomposition of biologically-based materials other than fossil fuels. During the
20 course of deliberations, the SAB Panel reviewed background materials provided by the Office of
21 Air and Radiation and heard from numerous public commenters. This Executive Summary
22 highlights the SAB's main conclusions. Detailed responses to the individual charge questions are
23 provided in the body of the report.
24

25 *Context*

26
27 EPA provided very little written description of its motivation for the *Framework* in the document
28 itself. However, through the background information provided and discussion at the public
29 meeting on October 25 – 27, 0211, EPA explained that the context for the report is the treatment
30 of biogenic CO₂ emissions in stationary source regulation. Specifically, under the Clean air Act,
31 stationary sources (e.g. power plants) are often regulated at the point of emissions. In the case of
32 greenhouse gases and this Framework, the question EPA is considering is whether and how to
33 count the biogenic CO₂ emissions from a stationary source.
34

35 On June 3, 2010, EPA finalized new thresholds for greenhouse gas emissions that define when
36 Clean Air Act permits under the New Source Review (Prevention of Significant Deterioration
37 program) and Title V operations permits program would be required (also known as the
38 "Tailoring Rule". In the Tailoring Rule, EPA did not exclude biogenic emissions from the
39 determination of applicability thresholds, however in July 2011, EPA deferred for a period of
40 three years the application of permitting requirements to biogenic carbon dioxide (CO₂)
41 emissions from bioenergy and other biogenic stationary sources. In its deferral, EPA committed
42 to conducting a detailed examination of the science and technical issues associated with biogenic
43 CO₂ emissions and submitting its study for review by the Science Advisory Board. The
44 motivation for considering whether or not to adjust biogenic carbon emissions from stationary
45 sources stems from the way the carbon in these feedstocks interacts with the global carbon cycle.
46 Plants take up carbon from the atmosphere to produce products that are consumed by humans

1 and animals for food, shelter and energy. Plants convert raw materials present in the ecosystem
2 such as carbon from the atmosphere and inorganic minerals and compounds from the soil
3 including nitrogen, potassium, and iron and make these elemental nutrients available to other life
4 forms. Carbon is returned to the atmosphere through respiration by plants and animals and by
5 industrial processes, including combustion and by natural decomposition. Thus, the use of
6 biogenic feedstocks results in both carbon emissions and carbon sequestration.

7 8 *Categorical inclusion or exclusion* 9

10 The SAB Panel was asked whether it supported EPA’s conclusion that categorical approaches
11 are inappropriate for the treatment of biogenic carbon emissions. A categorical inclusion would
12 treat biogenic carbon emissions as equivalent to fossil fuel emissions while a categorical
13 exclusion would exempt biogenic carbon emissions from greenhouse gas regulation. The
14 decision about a categorical inclusion or exclusion will likely involve many considerations that
15 fall outside the SAB’s scientific purview such as legality, feasibility and, possibly, political will.
16 The SAB cannot speak to the legal or implementation difficulties that could accompany any
17 policy on biogenic carbon emissions but this Advisory offers some scientific observations that
18 may inform the Administrator’s policy decision.

19
20 Carbon neutrality cannot be assumed for all biomass energy a priori. A blanket assumption of
21 carbon neutrality will underestimate the climate impact of bioenergy. There are circumstances in
22 which biomass is grown, harvested and combusted in a carbon neutral fashion but carbon
23 neutrality is not an appropriate a priori assumption; it is a conclusion that should be reached only
24 after considering a particular feedstock’s production and consumption cycle. There is
25 considerable heterogeneity in feedstock types, sources and production methods and thus net
26 biogenic carbon emissions will vary considerably. Only when bioenergy results in additional
27 carbon being sequestered above and beyond the anticipated baseline (the “business as usual”
28 trajectory) can there be a justification for concluding that such energy use results in little or no
29 increase in carbon emissions.

30
31 Given that some biomass could have positive net emissions, a categorical exclusion would
32 remove any responsibility on the stationary source for CO₂ emissions from its use of biogenic
33 material from the entire system (*i.e.*, the global economy) and provide no incentive for the
34 development and use of best management practices. Conversely, a categorical inclusion would
35 provide no incentive for using biogenic sources that compare favorably to fossil energy in terms
36 of greenhouse gas emissions.

37 38 *Biogenic Accounting Factor (BAF) Calculation* 39

40 The *Framework* presented an alternative to a categorical inclusion or exclusion by offering an
41 equation for calculating a Biogenic Accounting Factor (BAF) that adjusts the onsite biogenic
42 emissions at the stationary source based on feedstock growth, decomposition, carbon stored in
43 products, leakage and site sequestration effects. In consideration of its own regulatory
44 boundaries, EPA constrained BAF to lie somewhere between 0 (categorical exclusion) and 1
45 (categorical inclusion) however scientifically, BAF could be below 0 or above 1. In terms of
46 their greenhouse gas implications, some feedstocks could be better than carbon neutral and other

1 feedstocks might do more harm than fossil fuels. In keeping with its regulatory boundaries,
2 EPA's constrained BAF to lie at or above 0 because it was not allowing for the possibility of
3 granting credits to bioenergy if it creates net emissions reductions. EPA did not allow BAF to
4 rise above 1 because it was not considering the possibility of "penalizing" biogenic energy that
5 might be "dirtier" than fossil fuels. As a result of this artificial constraint on BAF, EPA's
6 *Framework* could, inadvertently, encourage the use of biological feedstocks that have higher
7 greenhouse gas emissions than fossil fuels just as it could, inadvertently, discourage the use of
8 biogenic feedstocks that are superior to fossil fuels in terms of their greenhouse gas
9 consequences.

10
11 To calculate BAF for biomass from roundwood trees, EPA conjured the concept of regional
12 carbon stocks (with the regions unspecified) and posed a "rule" whereby any bioenergy usage
13 that takes place in a region where carbon stocks are increasing would be automatically assigned a
14 BAF of 0. This leads to the nonsensical conclusion that a ton of carbon emitted in one part of the
15 country may be treated differently from a ton of carbon emitted elsewhere. The atmospheric
16 response to an additional ton of carbon is the same, regardless of its geographic origin. Thus,
17 EPA's creation of artificially contrived regions and the assignment of BAF based on geography
18 is not justified scientifically.

19
20 While EPA's proposed equation for BAF has overarching problems, the variables in the equation
21 capture many of the factors necessary for estimating the offsite carbon change associated with
22 stationary source biomass emissions from agricultural feedstocks. These include factors to
23 represent the carbon embodied in products leaving a stationary source, the proportion of
24 feedstock lost in conveyance, the offset represented by sequestration, the site-level difference in
25 net carbon flux as a result of harvesting, the emissions that would occur anyway from removal or
26 diversion of nongrowing feedstocks (e.g. corn stover) and other variables. For short recovery
27 feedstocks where carbon recovery and "anyway" emissions are within one to a few years (i.e.,
28 agricultural residues, perennial herbaceous crops, mill wood wastes, other wastes), the
29 *Framework* may, with some adjustments and appropriate data, accurately represent direct carbon
30 changes in a particular region. For waste materials (municipal solid waste), the *Framework*
31 needs to consider the mix between biogenic and fossil carbon as well as the potential capture of
32 methane (CH₄) emissions from landfills. Given that CH₄ emissions from landfills are often
33 captured, crediting waste material for avoided emissions (as the *Framework* currently does) may
34 not always be appropriate. For long carbon recovery feedstocks (roundwood), the *Framework*
35 does not capture the carbon outcome given its omission of the time path for carbon recovery
36 following harvest. For these feedstocks, the *Framework* does not allow determination of the
37 incremental impact of a stationary facility holding everything else the same or establish causality
38 between bioenergy use and observed carbon outcomes. Additionally, the measurement of the
39 carbon impact of the facility is scale sensitive. These issues are discussed in greater detail below.

40
41
42 Leakage is a phenomenon by which efforts to reduce emissions in one place shift emissions to
43 another location or sector. The *Framework's* equation for BAF includes a term for leakage,
44 however EPA decided that calculating values for leakage was outside the scope of the
45 *Framework*. It should be recognized that incorporating leakage, however difficult, may change
46 the BAF results radically. "Bad" leakage (called "positive" leakage in the literature) occurs

1 when the use of biogenic feedstocks causes price changes which, in turn, drive changes in
2 consumption and production outside the boundary of the stationary source, even globally, that
3 lead to increased carbon emissions. One type of positive leakage could occur if land is diverted
4 from food/feed production to bioenergy production which increases the price of conventional
5 agricultural and forest products in the world market and leads to conversion of carbon rich lands
6 to crop production and the release of carbon stored in soils and vegetation.. The use of biogenic
7 feedstocks can also affect the price of fossil fuels by lowering demand for them and thereby
8 increasing their consumption elsewhere. “Good” leakage (called “negative” leakage in the
9 literature) could occur if the use of biomass leads to carbon offsetting activities elsewhere. The
10 latter could arise for example, if increased demand for biomass and higher prices generates
11 incentives for investment in forest management which increases forest carbon sequestration.

12
13 The existing literature in the social sciences shows that the overall magnitude of leakage is
14 highly uncertain and differs considerably across studies and within a study, depending on
15 underlying assumptions. Rather than eschewing the calculation of leakage altogether, EPA could
16 instead, try to ascertain the directionality of net leakage, whether it is positive (leading to
17 increased carbon emissions elsewhere) or negative (leading to carbon offsetting activities) and
18 incorporate that information in its decision making. Moreover, EPA should investigate leakage
19 that may occur in other media, e.g. fertilizer runoff into waterways. In cases where prior
20 research has indicated directionality, if not magnitude, such information should be used.

21 22 *Causality and Additionality*

23
24 EPA’s stated objective was to accurately reflect the carbon outcome of biomass use by stationary
25 sources. To accurately capture the carbon outcome, this requires selecting a time period and
26 determining what would have happened anyway without the harvesting and comparing that
27 impact with the carbon trajectory associated with harvesting of biomass for bioenergy within that
28 time frame. Although any “business as usual” projection would be uncertain, it is the only
29 means by which to gauge the incremental impact of biomass harvesting. The *Accounting*
30 *Framework* discusses this approach, calling it an “anticipated future baseline” approach but does
31 not attempt it. Instead a fixed reference point and an assumption of geographic regions were
32 chosen to determine the baseline for whether biomass harvesting for bioenergy facilities is
33 having a negative impact on the carbon cycle. The choice of a fixed reference point may be the
34 simplest to execute, but it does not properly address the additionality question, i.e. the extent to
35 which forest stocks would have been growing or declining over time in the absence of bioenergy.
36 The use of a fixed reference point baseline coupled with a division of the country into regions
37 implies that forest biomass emissions could be considered carbon neutral simply because forest
38 stocks are increasing in a particular region from the base year. This is not justified scientifically
39 because from a mass balance perspective, a reduction in the rate of increase of carbon stocks is
40 equivalent to an increase in emissions; rather it is an artifact based on the choice of baseline and
41 the assumption of unspecified geographic regions. The reference point estimate of regionwide
42 net emissions or net sequestration does not indicate, or estimate, the difference in greenhouse gas
43 emissions (the actual carbon gains and losses) over time that are associated with biomass use.
44 Instead, the *Framework* captures changes over an undefined space, in a sense, substituting space
45 for time. As a result, the *Framework* fails to capture the causal connection between biomass
46 harvesting and atmospheric impacts.

1
2 By forgoing the anticipated future baseline approach, the *Framework* fails to capture the
3 difference in CO₂ concentrations the atmosphere sees over some time frame as a result of
4 stationary source use of forest biomass. For faster growing biomass like agricultural crops, the
5 incorporation of a time frame is not necessary. For wood harvested specifically for energy use
6 (roundwood) and logging residues, the *Framework* does not incorporate a) the time path of
7 carbon accumulation in forests (before or after energy emissions from harvested roundwood) or
8 b) the time path of the “anyway” emissions that would have occurred on the land if logging
9 residue were not used for energy production. By not incorporating a time interval, the
10 *Framework* fails to capture the contribution to climate change made by temporary carbon losses.
11 Thus for long recovery feedstocks where carbon recovery occurs over decades, the *Framework*
12 does not capture the carbon outcome, defined as “what the atmosphere sees.” EPA might
13 consider adopting a GWP index to represent feedstocks with long recovery times. As pioneered
14 by Cherubini *et al.* (2011), GWP_{bio} incorporates a time dimension into the calculation, taking
15 into account the fact that sequestration in new growth is spread over a time interval of years.
16 GWP_{bio} is a unit-based index that uses CO₂ impulse response functions from C cycle models in
17 the elaboration of atmospheric decay functions for biomass-derived CO₂ emissions. GWP_{bio} is
18 expressed as a function of the rotation period of the biomass.

19 20 *Scale*

21
22 The use of a regional scale is a central weakness of the *Framework*. EPA employed regions as
23 an artificial construct to avoid the need for site-specific chain of custody carbon accounting with
24 separate streams for each feedstock and as an alternative to capturing changes in carbon stocks
25 over time. EPA used a variable for the Level of Atmospheric Reduction (LAR) to capture the
26 proportion of potential gross emissions that are offset by sequestration during feedstock growth,
27 however the calculation of LAR captures landscape wide changes rather than facility-specific
28 carbon emissions associated with actual fuelsheds. However, it makes the estimate of the BAFs
29 sensitive to the choice of the spatial region. As shown in EPA’s own case study, the choice of the
30 appropriate regional scale has significant implications for the emissions attributed to a facility.

31 32 *Recommendations for Revising BAF*

33
34 To implement the *Framework*, EPA faces daunting technical challenges. Although the SAB
35 would prefer an alternative to the calculation of a BAF (as described below), if EPA decides to
36 revise the *Framework*, the SAB recommends the following improvements.

- 37
38 • Develop a separate BAF equation for each feedstock category. Feedstocks could
39 be categorized into short rotation dedicated energy crops, crop residues, forest
40 residues, long rotation trees and waste materials.
- 41 • Separate out feedstocks which could be classified as “anyway” emissions so that
42 their BAF would automatically be either set to 0 or modeled as a decay function.
- 43 • Develop an equation for perennial energy crops and short rotation woody
44 biomass.

- 1 • Use an anticipated baseline approach for long recovery feedstocks like
2 roundwood.
 - 3 ▪ For forest biomass from roundwood harvested for bioenergy, omit the
4 regional scale and incorporate a time dimension, modifying certain factors
5 in the BAF equation to include the timescale over which carbon is
6 decomposed or released back to the atmosphere. Consider employing
7 integrated forest sector models and/or Cherubini's GWP_{bio} .
 - 8 ▪ Modify the variable that represents the proportion of emissions that are
9 offset by sequestration during feedstock growth (LAR) so that it is scale
10 insensitive.
- 11 • Develop an equation for municipal solid waste to take into account the mix of
12 biogenic waste with fossil fuel waste as well as the possibility of methane capture
13 in landfills.
- 14 • Consider information about the directionality of leakage as well as leakage into
15 other media.

18 *Alternatives to BAF*

19
20 In a perfect world with full information and unlimited policy choices, carbon limits (or prices)
21 would be implemented economy-wide and not selectively enacted for particular sources or
22 sectors. Economic research has shown that the most cost-effective way to reduce greenhouse gas
23 emissions (or any other pollution) is to regulate or tax across all sources until they face a
24 marginal cost of emissions reduction that equals the marginal benefit of emissions reduction and
25 is equal across sources. In EPA's less perfect world with limited authority under the Clean Air
26 Act, the most efficient economy-wide solution is not within its menu of choices. EPA's
27 regulation of stationary sources will exclude other users of biomass (e.g. consumers of ethanol)
28 that have equivalent impacts on the carbon cycle as well as downstream consumers of products
29 produced by these facilities.

30
31 In this second-best world with limited policy instruments that can be applied only to limited
32 sources, it would be desirable for EPA to ascribe all changes in greenhouse gas emissions (both
33 upstream and downstream of the stationary source) caused by the operation of the stationary
34 facility to that source. Ideally, these emissions would need to be determined on a facility-
35 specific basis however facility-specific calculations face some daunting practical challenges,
36 including chain of custody accounting and estimation of market mediated effects or "leakage."
37

38 Given the choices facing EPA, one hybrid approach for EPA to consider would be a categorical
39 inclusion with opt-out provisions. Stationary sources would be subject to a categorical inclusion
40 unless they opted out by certifying that their biomass was sustainably harvested and produced
41 using best management practices. By making the stationary source responsible for
42 demonstrating "sustainability", the source would be linked to its land base. This would remove
43 the perverse situation of a responsible bioenergy facility, using feedstock produced in a highly
44 sustainable manner, being penalized because it happens to be located in a region where other,
45 less sustainable forest activities are causing carbon stocks to decline. It would also avoid the

1 problem of a bioenergy facility that uses biomass harvested in an unsustainable manner
2 benefiting from operating in a region where carbon stocks happen to be growing. A certification
3 system may not control for market-mediated effects or leakage and it may increase complexity
4 and costs of accounting for the carbon emissions of a stationary source. The SAB cannot offer
5 an opinion on the legal feasibility of such an approach. Certification systems have been
6 successfully employed in Europe and, to a lesser extent, in the U.S. via the Sustainable Forestry
7 Initiative.

8
9 Given the conceptual deficiencies, described above, and prospective difficulties with
10 implementation, the SAB urges the Agency to “think outside the box” about policy options that
11 go beyond categorical inclusion, exclusion or calculating a BAF for each facility. We offer the
12 following three options for the Agency’s consideration:

- 13
- 14 1. Consider developing a generic BAF for each feedstock category.
- 15 2. Consider certification systems.
- 16 3. Consider offset systems.
- 17

18 Option 1: Consider developing a generic BAF for each feedstock category. An alternative to
19 revising the *Framework* and calculating a BAF for each stationary facility is to develop general
20 BAFs for each category of feedstocks, differentiating among feedstocks using general
21 information on how their harvest and combustion interacts with the carbon cycle. EPA might
22 need to develop a separate BAF equation for each of the other categories of feedstocks, using
23 forest growth models to plot carbon paths that track regrowth following harvest. Many more
24 case studies would be needed to develop an accounting focused on feedstocks rather than the
25 facility. These generic BAFs would be applied by stationary facilities to determine their quantity
26 of biogenic emissions that would be subject to EPA’s tailoring rule.

27
28 Option 2: Consider certification systems in a hybrid approach. A categorical inclusion with an
29 opt-out provision whereby facilities could opt out by certifying that their biomass was
30 sustainably harvest and produced using best management practices. Such “sustainability” would
31 need to be certified by an authority using valid scientific measurements. Requiring stationary
32 facilities to use only “certified” feedstocks would be administratively simpler than quantifying a
33 specific net change in greenhouse gases associated with a particular stationary facility.
34 Certification approach can avoid the arbitrary scale issues and can perhaps avoid or reduce
35 leakage.

36
37 Option 3: Consider offsets. An offset is a reduction in emissions of carbon dioxide or other
38 greenhouse gas made in order to offset an emission made elsewhere. The use of offsets could
39 accompany either Option 1 or Option 2 above or even a calculated BAF for each facility (using
40 the *Framework*). If offsets were allowed, it would make possible a variety of gains from trade
41 that facilities could use to lower costs. For example, a fossil or biogenic CO₂ emitter could
42 contract with land owners to offset their emissions through forest protection and regrowth or
43 carbon accumulation in soils.

44
45 *Conclusion*

1 As EPA has recognized, the greenhouse gas implications of bioenergy are more complex and
2 subtle than the greenhouse gas impacts of fossil fuels. In recognition of the complicated role that
3 bioenergy plays in the carbon cycle, the *Framework* provides a structure to account for net
4 climate impacts. The focus of the *Framework*, however, is on point source emissions from
5 stationary facilities. As a result, the *Framework's* boundaries are drawn only so far as to account
6 for any offsetting carbon sequestration that may be attributed to the facility's use of a biogenic
7 feedstock. These narrow regulatory boundaries are in conflict with a more comprehensive
8 carbon accounting that considers the entire carbon cycle and the possibility of gains from trade
9 between sources, among sources or between sources and sinks. As far as the climate is
10 concerned, it makes no difference if land use change is used to offset CO₂ that was of fossil
11 origin or of biogenic origin. By staying within boundaries drawn narrowly around the stationary
12 source, the *Framework* eclipses a more comprehensive approach to greenhouse gas reductions
13 that would address all sources and sinks. While the *Framework*, to some degree, extends carbon
14 accounting upstream, a more comprehensive carbon accounting would extend downstream—to
15 emissions from by-products, co-products, or products such as ethanol combustion or ethanol by-
16 products such as dried distillers grains (DDGs) that are sold as livestock feed and will soon
17 become CO₂ (or CH₄). It would also extend upstream and account for the carbon emissions due
18 to the use of fertilizer to produce the biogenic feedstock.

19
20 The *Framework's* main contribution is to lay the groundwork for future developments in
21 accounting for biogenic emissions while forcing important questions.

22

2

3 **1. In reviewing the scientific literature on biogenic CO₂ emissions, EPA assessed the**
4 **underlying science of the carbon cycle, characterized fossil and biogenic carbon**
5 **reservoirs, and discussed the implications for biogenic CO₂ accounting.**
6

7 **1.1. Does the SAB support EPA’s assessment and characterization of the underlying**
8 **science and the implications for biogenic CO₂ accounting?**
9

10
11 EPA has done an admirable job of reviewing the science behind the carbon cycle and greenhouse
12 gas emissions and their relationship to climate change, extracting some of the critical points that
13 are needed to create the proposed accounting framework. At the same time, there are several
14 important scientific issues that are not addressed in the EPA document, as well as scientific
15 issues that are briefly discussed but not sufficiently explored in terms of how they relate to the
16 *Framework*. In the following section, we describe a series of deficiencies with the EPA
17 assessment and characterization of the science behind biogenic CO₂ accounting, and suggest
18 some areas where the treatment of the existing scientific understanding of ecosystems and the
19 carbon cycle could be strengthened.
20

21 1) Timescale
22

23 One fundamental deficiency in the EPA report is the lack of discussion of the different
24 timescales inherent in the carbon cycle and the climate system that are critical for establishing an
25 accounting system. This is a complicated subject because there are many different timescales
26 that are important for the issues associated with biogenic carbon emissions. At the global scale,
27 there are multiple timescales associated with mixing of carbon throughout the different reservoirs
28 on the Earth’s surface. When carbon dioxide is released into the air from burning fossil fuels,
29 roughly 45% stays in the air over the course of the following year. Of the 55% that is removed,
30 roughly half is taken up by the ocean, mostly in the form of bicarbonate ion, and the other half is
31 taken up by the terrestrial biosphere, primarily through reforestation and enhanced
32 photosynthesis. The airborne fraction (defined as the fraction of emissions that remains in the
33 air) has been remarkably constant over the last two decades.
34

35 There is considerable uncertainty over how the magnitude of ocean and terrestrial uptake will
36 change as the climate warms during this century. If the entire ocean were to instantly reach
37 chemical equilibrium with the atmosphere, the airborne fraction would be reduced to 20% to
38 40% of cumulative emissions, with a higher fraction remaining in scenarios with higher
39 cumulative emissions. In other words, the ocean chemical system by itself cannot remove all
40 the CO₂ released in the atmosphere. Because carbon uptake by the ocean is limited by the rate of
41 mixing between the shallow and deeper waters, this complete equilibration is expected to take
42 thousands of years. Over this century, if global CO₂ emissions continue to rise, most models
43 predict that ocean uptake will stabilize between 3 to 5 GtC/y, implying that the fraction of
44 emissions taken up by the ocean will decrease. For the terrestrial biosphere, there is a much
45 wider envelope of uncertainty; some models predict that CO₂ uptake will continue to keep pace
46 with the growth in emissions, while other models suggest that CO₂ uptake will decline, even

1 becoming a net source of CO₂ to the atmosphere if processes such as release of carbon from the
2 tundra or aridification of the tropics were to occur.

3
4 Over the timescale of several thousand years, once ocean equilibration is complete and only 20%
5 to 40% of cumulative emissions remains in the atmosphere, dissolution of carbonate rocks on
6 land and on the ocean floor will further reduce the airborne fraction to 10% to 25% over several
7 thousand years to ten thousand years. This last remnant of anthropogenic CO₂ emissions will
8 stay in the atmosphere for more than 100,000 years, slowly drawn down by silicate weathering
9 that converts the CO₂ to calcium carbonate, as well as slow burial of organic carbon on the ocean
10 floor. The size of this “tail” of anthropogenic CO₂ depends on the cumulative emissions of CO₂,
11 with higher cumulative emissions resulting in a higher fraction remaining in the atmosphere.

12
13 Another important timescale for considering accounting systems for biogenic carbon emissions
14 is the period over which the climate responds to carbon dioxide and other greenhouse gases.
15 Several different climate modeling studies have demonstrated that the peak warming in response
16 to greenhouse gas emissions is primarily sensitive to cumulative greenhouse gas emissions over
17 a period of roughly 100 years, and is relatively insensitive to the emissions pathway within that
18 time frame. What this means is that an intervention in forests or farming that results in a
19 change in storage of carbon or emissions reductions must endure for significantly longer than
20 100 years in order to have any real influence on the peak climate response.

21
22 Timescales are also important at a more local scale. Given the EPA's objective is to account for
23 the atmospheric impact of biogenic emissions, it is important to consider the turnover times of
24 different biogenic feedstocks in justifying how they are incorporated into the accounting
25 framework. The fundamental differences in stocks and their turnover times as they relate to
26 impact on the atmosphere is not well discussed or linked into the current framework. (Page 6
27 raises the issue but does not delve into what it means for biogenic carbon accounting).

28 If a carbon stock is cycling quickly on land, turning over and being replaced fully in less than
29 100 years (as discussed above), it may have a beneficial impact when it is consumed for energy,
30 displacing the combustion of fossil fuel. If the carbon stock, or some part of it, turns over more
31 slowly, i.e., much longer than 100 years, the timing of release begins to matter.

32 There is a continuum of carbon stock size and turnover among the biogenic feedstock sources
33 included in this framework, but there is little background discussion of the variation in the stock
34 and turnover and how that informs the accounting method. The current framework sets up
35 categories of feed stocks based on their source, but these groupings have little to do with their
36 carbon stock and turnover or how they are accounted for in the current framework. The science
37 section could walk through the carbon stocks covered by the scope of the accounting framework
38 and their relevant turnover times.

39
40 The timescale over which land carbon may change, coupled with the scientific understanding of
41 the timescale of the climate system response, could have been used in the report to support the
42 EPA accounting method against criticisms from several environmental groups who point to the
43 idea of a carbon debt when biomass is harvested and taken from a forest. The idea of a carbon
44 debt is technically correct, but fails to recognize that the climate response is based on cumulative
45 emissions over 100 years. This means that the climate system is not sensitive to the imbalance in
46 the carbon cycle that might occur over decades from harvesting of biomass for bioenergy

1 facilities. The carbon debt is a serious problem if the time for regrowth is much more than 100
2 years. However, the annual accounting method proposed by the EPA does not fit well with this
3 framework. A scientifically rigorous evaluation of the biomass harvest on the carbon cycle must
4 consider what the impact will be on the 100 year timescale. Annual accounting of carbon stocks
5 is likely to give inaccurate assessments of the overall carbon cycle impacts.

6
7 A subtle but important point for estimating carbon outcome and “what the atmosphere see” is
8 that the measurement should be in the form of change in global warming potential on say the
9 commonly used 100 year basis. For short recovery time feedstocks such as perennial grasses the
10 difference in global warming potential is almost identical to CO₂ emissions minus carbon change
11 on the land (CO₂ eq). For feedstocks with long recovery time one must compute the change in
12 global warming potential by calculating the cumulative radiative forcing of the initial CO₂
13 emission minus the carbon change on the land (CO₂ eq) (using an integral convolution) to 100
14 years, then dividing by the integral of radiative forcing for a simple CO₂ emission to 100 years.
15 This estimate of GWP in CO₂ equivalents will be less than an estimate using CO₂ emission
16 minus carbon change on the land (CO₂ eq) over 100 years. The more detailed calculation of
17 change in GWP₁₀₀ properly takes into account absorption of the initial CO₂ emission by oceans
18 and terrestrial CO₂ fertilization.

21 2. Disturbance

22 Because ecosystems respond in complicated ways to disturbances (e.g. harvesting, fire) over
23 long periods of time, and with a high degree of spatial heterogeneity, the state of knowledge
24 about disturbance and impacts on carbon stocks and turnover should be reviewed within the
25 context of relevant timescales. This is highly relevant to producing accurate estimates of
26 biogenic emissions from the land. There is also insufficient treatment given to the existing
27 literature on the impact of different land management strategies on soil carbon, which is
28 important for understanding how carbon stocks may change over many decades. A short list of
29 relevant publications is provided in the Reference section.

31 3. Space for time substitution

32
33 A discussion of the literature on the value and limitations of space for time substitutions should
34 be discussed as it is a fundamental part of the *Accounting Framework* presented. The
35 implications for different baseline conditions on space-time substitution should also be part of
36 this methods review.

38 4. Non-CO₂ Greenhouse Gases

39
40 The *Framework* does not incorporate greenhouse gases other than CO₂. This fails to account for
41 the difference between biomass feedstocks in terms of their production of other greenhouse
42 gases. The most important of these is likely to be N₂O produced by the application of fertilizer
43 (Crutzen et al., 2007). In particular, if the biomass feedstock is from an energy crop that results
44 in different N₂O emissions vis-a-vis other crops, should this be counted? Is it negligible? This
45 issue is not introduced in the science section. N₂O is relatively long-lived (unlike methane), and
46 therefore the climate impacts of heavily fertilized biomass (whether in forests or farms) are

1 greater than non-fertilized biomass. There is a substantial literature on N₂O from fertilizer use
2 that was not discussed in the *Framework*. If this is a life cycle comparability/fairness issue with
3 fossil fuels this needs to be explicitly discussed. If we are not counting certain emissions from
4 fossil fuels either because they are counted elsewhere or outside the mandate, then how do those
5 compare to the emissions from biogenic fuels that are counted elsewhere or outside the mandate?
6 How significant are they compared to those emitted and counted?

7
8
9

1 **Charge Question 2**
2

3 **2. Evaluation of biogenic CO₂ accounting approaches**
4

5 **In this report, EPA considered existing accounting approaches in terms of their ability to**
6 **reflect the underlying science of the carbon cycle and also evaluated these approaches on**
7 **whether or not they could be readily and rigorously applied in a stationary source context**
8 **in which onsite emissions are the primary focus. On the basis of these considerations, EPA**
9 **concluded that a new accounting framework is needed for stationary sources.**

10
11 **2.1. Does the SAB agree with EPA's concerns about applying the IPCC national**
12 **approach to biogenic CO₂ emissions at individual stationary sources?**
13

14 Yes. The IPCC national approach is a inventory of global greenhouse emissions (*i.e.*, all
15 emissions are counted). It is comprehensive in quantifying all emissions sources and sinks, but
16 does not describe linkages among supply chains. In other words, it is essentially a “production-
17 based inventory” or “geographic inventory” rather than a “consumption-based inventory”
18 (Stanton *et. al.*, 2011. Moreover, it offers a static snapshot of emissions at any given time, but it
19 does not expressly show changes in emissions over time. As such, the IPCC national approach
20 does not explicitly link biogenic CO₂ emission sources and sinks to stationary sources, nor does
21 it provide a mechanism for measuring changes in emissions as a result of changes in the building
22 and operation of stationary sources using biomass.
23

24 **2.2. Does the SAB support the conclusion that the categorical approaches (inclusion and**
25 **exclusion) are inappropriate for this purpose, based on the characteristics of the**
26 **carbon cycle?**
27

28 Note that the Panel sought and got clarification from EPA that this question refers to “a priori”
29 categorical inclusion and exclusions as inappropriate.
30

31 A decision about a categorical inclusion or exclusion will likely involve many considerations
32 that fall outside the SAB’s scientific purview such as legality, feasibility and, possibly, political
33 will. The SAB cannot speak to the legal or implementation difficulties that could accompany
34 any policy on biogenic carbon emissions but below are some scientific observations that may
35 inform the Administrator’s policy decision.
36

37 The notion that biomass is carbon neutral arises from the fact that the carbon released as CO₂
38 upon combustion was previously removed from the atmosphere as CO₂ during plant growth.
39 Thus, the physical flow of carbon in the biomass combusted for bioenergy represents a closed
40 loop that passes through a stationary source. Under an accounting framework where life cycle
41 emissions associated with the production and use of biomass are attributed to a stationary source,
42 assuming carbon neutrality of biomass necessarily implies that the net sum of carbon emissions
43 from all sources and sinks is zero, including all supply chain and market-mediated effects.
44 Therefore, carbon neutrality cannot be assumed for all biomass energy a priori (Rabl et al., 2007;
45 Johnson, 2009, Searchinger et. al, 2009). There are circumstances in which biomass is grown,
46 harvested and combusted in a carbon neutral fashion but carbon neutrality is not an appropriate a

1 priori assumption; it is a conclusion that should be reached only after considering a particular
2 feedstock production and consumption cycle. There is considerable heterogeneity in feedstock
3 types, sources, production methods and leakage effects; thus net biogenic carbon emissions will
4 vary considerably.

5
6 Given that some biomass could have positive net emissions, a categorical exclusion would
7 remove any responsibility on the stationary source for CO₂ emissions from its use of biogenic
8 material from the entire system (*i.e.*, the global economy) and provide no incentive for the
9 development and use of best management practices. Conversely, a categorical inclusion would
10 provide no incentive for using biogenic sources that compare favorably to fossil energy in terms
11 of greenhouse gas emissions.

12
13 **2.3. Does the SAB support EPA's conclusion that a new framework is needed for**
14 **situations in which only onsite emissions are considered for non-biologically-based**
15 **(i.e., fossil) feedstocks?**

16
17 Through discussions with the Agency at the public meeting, EPA agreed that this question is
18 redundant with other charge questions and therefore does not need to be answered here.

19
20 **2.4. Are there additional accounting approaches that could be applied in the context of**
21 **biogenic CO₂ emissions from stationary sources that should have been evaluated**
22 **but were not?**

23
24 Several other agencies are developing methods for assessing greenhouse gas emissions by
25 facilities that could inform the approach developed by the EPA. These include the DOE 1605(b)
26 voluntary greenhouse gas registry targeted to entities which has many similar characteristics to
27 the approach proposed by EPA for stationary sources. There is also the Climate Action Registry
28 developed in California that uses a regional approach to calculate baselines based on inventory
29 data and may inform the delineation of geographic regions and choice of baselines in the EPA
30 approach. USDA is also developing in parallel an accounting approach for forestry and
31 agricultural landowners. It would be beneficial if the EPA and USDA approaches could be
32 harmonized to avoid conflicts and take advantage of opportunities for synergy.

1 **Charge Question 3**
2

3 **3. Evaluation of methodological issues. EPA identified and evaluated a series of factors in**
4 **addition to direct biogenic CO₂ emissions from a stationary source that may influence**
5 **the changes in carbon stocks that occur offsite, beyond the stationary source (e.g.,**
6 **changes in carbon stocks, emissions due to land-use and land management change,**
7 **temporal and spatial scales, feedstock categorization) that are related to the carbon**
8 **cycle and should be considered when developing a framework to adjust total onsite**
9 **emissions from a stationary source.**

10
11 **3.1. Does SAB support EPA’s conclusions on how these factors should be included in**
12 **accounting for biogenic CO₂ emissions, taking into consideration recent advances**
13 **and studies relevant to biogenic CO₂ accounting?**
14

15 For agricultural feedstocks, the factors identified by EPA to adjust the CO₂ emissions from a
16 stationary source for direct off-site changes in carbon stocks are appropriate but suffer from
17 significant estimation and implementation problems.
18

19 Municipal solid waste biomass is either disposed of in a landfill or combusted in facilities at
20 which energy is recovered. Smaller amounts of certain waste components (food and yard waste)
21 may be processed by anaerobic digestion and composting. The CO₂ released from the
22 decomposition of biogenic waste in landfills, compost facilities or anaerobic digesters could
23 reasonably be assigned a BAF of 0 but applying a 0 to all municipal solid waste does not take
24 into account the fact that when waste is burned for energy recovery, both fossil and biogenic CO
25 are released. The *Framework* should take into account the mix of biogenic waste with fossil fuel
26 waste since the combustion of municipal solid waste results in the production of both biogenic
27 and fossil carbon. In addition, the *Framework* should account for the fact that CH₄ emissions
28 from landfills are sometimes captured already.
29

30 For forest-derived woody biomass, the calculation of BAF would need to account for the time
31 path of carbon recovery and emissions from logging residue. The *Framework* recognizes some
32 of the challenges associated with defining the spatial and temporal timescale and in choosing the
33 appropriate baseline but ultimately chooses an approach that disregards any consideration of the
34 timescales over which biogenic carbon stocks are accumulated or depleted. Instead the
35 *Framework* substitutes a spatial dimension for time in assessing carbon accumulation; and
36 creates an accounting system that generates outcomes sensitive to the regional scale at which
37 carbon emissions attributed to a stationary source are evaluated. Below are some comments on
38 particular factors.
39

40 Level of Atmospheric Reduction (LAR): The scientific justification for constraining the range of
41 LAR to be greater than 0 but less than 1 is not evident since it is possible for feedstock
42 production to exceed feedstock consumption. The term also combines two very separate
43 concepts, regrowth of feedstock (GROWTH) and avoided emissions (AVOIDEMIT) from the
44 use of residues that would have been decomposed and released carbon emissions anyway. These
45 two terms are not applicable together for a particular feedstock and representing them as additive

1 terms in the accounting equation can be confusing. Additionally, the value of LAR, for forest
2 biomass, is sensitive to the size of the region for which growth is compared to harvest.

3
4 Loss (L): This is included in the *Accounting Framework* to explicitly adjust the area needed to
5 provide the total feedstock for the stationary facility. It is a term used to include the emissions
6 generated by the feedstock lost during storage, handling and transit. This is based on the strong
7 assumption that most of the carbon in the feedstock lost during transit is immediately
8 decomposed and therefore released to the atmosphere, an assumption that lacks scientific
9 justification. It is therefore important to separate the use of this Loss term for estimating the area
10 needed to provide the feedstock and for estimating the carbon emissions released by the
11 operation of the stationary source. To more accurately estimate the actual loss of carbon due to
12 these losses one would need to model the carbon storage and fluxes associated with the feedstock
13 lost, which is likely to be a function of time. The number of years considered would be a policy
14 decision; the longer the period, the larger the proportion of the loss that would be counted. The
15 *Accounting Framework* tacitly assumes an infinitely long horizon that results in the release of all
16 the carbon stored in the lost feedstock.

17
18 Products (PRODC). The removal of products from potential gross emissions is justified
19 scientifically, however, the scientific justification for treating all products equally in terms of
20 their impact on emissions is not clear. In the case of some products (e.g., fuels like ethanol and
21 paper) the stored carbon will be released rapidly while in the case of other products such as
22 furniture it might be released over a longer period of time. The *Framework* implicitly assumes
23 that all products have infinite life-spans, an assumption with no scientific foundation. For
24 products that release their stored carbon rapidly, the consequences for the atmosphere are the
25 same as those associated with the carbon stored in the underlying feedstock; thus a distinction
26 between the two is not scientifically justified. To precisely estimate the stores of products so as
27 to estimate the amount released, one would need to track the stores as well as the fluxes
28 associated with products pools. The stores of products could be approximated by modeling the
29 amount stored over a specified period of time; the exact time period would have to be a policy
30 decision.

31
32 A second way in which PRODC is used is as a means of pro-rating all area based terms such as
33 LAR, Site-TNC and Leakage. This is potentially problematic because it makes the emissions
34 embodied in co-products dependent on the choice of regional scale at which LAR is estimated.
35 As the size of the region contracts, LAR tends towards zero and the amount of gross emissions
36 embodied in PRODC increases and exacerbates the implications of the scale sensitivity of the
37 LAR value.

38
39 Avoided Emissions (AVOIDEMIT): This term refers to transfers of emissions within the system
40 or to emissions that occur regardless, although in different places (i.e., at the point source or at
41 the field site). Since the concept reflected in “avoided emissions” is actually “equivalent field-
42 site emissions” it would be clearer to refer to it by a term that reflects the actual concept being
43 used. As with the Loss term, the assumption of instantaneous decomposition or total combustion
44 of the crop or forest residue needs scientific support. Some of the materials that are harvested
45 might take decades to centuries to fully decompose. To be scientifically-based the hypothetical
46 store of harvested fuel stock would have to be tracked. To approximate these stores one could

1 compute the average amount remaining after a period of years. The number of years considered
2 would be a policy decision; the longer the period, the less would be counted. The *Framework*
3 tacitly assumes an infinite number of years.

4
5 Sequestration (SEQP). Including sequestration in the *Framework* is appropriate. However, the
6 approach taken is subject to the same problems as those described for Products. There is no
7 scientific literature cited to support the idea that all the materials produced by biogenic fuel use
8 do not decompose. This is the subject of ongoing research, but it seems clear that these materials
9 do decompose. The solutions to creating a more realistic and scientifically justified estimate are
10 the same as for the Products term (see above).

11
12 Leakage. The *Framework* includes a term for leakage but is silent on the types of leakage that
13 would be included and how leakage would be measured. EPA said it was not providing a
14 quantification methodology for leakage because assessing leakage requires policy- and program-
15 specific details that are beyond the scope of the report. There are several conceptual and
16 implementation issues that merit further discussion in the *Framework*.

17
18 The use of biogenic feedstocks could lead to leakage by diverting feedstocks and land from other
19 uses and affecting the price of conventional forest and agricultural products which can lead to
20 indirect land use changes that release carbon stored in soils and vegetation. The use of these
21 feedstocks can also affect the price of fossil fuels by lowering demand for them and increasing
22 their consumption elsewhere. These leakage effects could be positive (if they lead to carbon
23 emissions elsewhere) or negative (if they lead to carbon uptake activities). The latter, could arise
24 for example, if increased demand for biomass and higher prices generates incentives for
25 investment in forest management that increases forest carbon sequestration. Some research has
26 shown that when a future demand signal is strong enough, expectations about biomass demand
27 for energy (and thus revenues) can reasonably be expected to produce anticipatory feedstock
28 production changes with associated changes in land management and land-use (e.g. Sedjo
29 forthcoming; Rose, McCarl, Latta, forthcoming). Thus price changes can lead to changes in
30 consumption and production decisions outside the boundary of the stationary source, even
31 globally.

32
33 While the existence of non-zero leakage is very plausible, the appropriateness of attributing
34 emissions that are not directly caused by a stationary facility to that facility is questionable.
35 While first principles in environmental economics show the efficiency gains from internalizing
36 externalities by attributing direct environmental damages to responsible parties that are directly
37 responsible for them, they do not unambiguously show the social efficiency gains from
38 attributing economic or environmental effects (such as leakage) that occur due to price changes
39 induced by its actions to that facility. Moreover, leakage caused by the use of fossil fuels is not
40 included in assessing fossil emissions generated by a stationary facility. Thus, the technical basis
41 for attributing leakage and inherent inconsistency involved in including leakage and the different
42 sources of leakage that will be included in this *Framework* needs to be assessed. Including
43 some types of leakage (for e.g., due to agricultural commodity markets) and not others (such as
44 those due to fossil fuel markets) and for biomass and not fossil fuels would be a policy decision
45 without the underlying science to support it.

46

1 The empirical assessment of the magnitude of leakage and the method for attributing it to
2 different stationary sources would need to be based on complex global economic modeling that
3 involves comparisons of production, consumption and land use decisions with the use of a
4 biogenic feedstock to those in a baseline scenario without the use of this feedstock. Thus it
5 would use an anticipated baseline. This approach would introduce an inconsistency between the
6 anticipated baseline that is needed to assess leakage and reference point baseline proposed for
7 assessing LAR. The existing literature in the social sciences that is assessing the magnitude of
8 leakage shows that its overall magnitude is highly uncertain and differs considerably across
9 studies and within a study depending on underlying assumptions.

10
11 The use of a regional scale for assessing LAR implies that there could be cross-regional leakage;
12 its presence and magnitude will be a function of the characteristics of the regions created (size
13 and composition). The more regions created from a given area, the more leakage will occur from
14 each region. If this leakage is not accounted for elsewhere in the *Framework*, for e.g., increased
15 harvesting of biomass for pulp and paper manufacture in one region due the operations of a
16 stationary facility in a different region, then this leakage could have an atmospheric outcome.
17 With many regions involved, it would become extremely difficult to determine which of the
18 multiple regions generated a particular leakage observed. Where many regions are involved
19 simultaneously, disturbances may make identifying the unique leakage from a particular region
20 almost impossible to determine. In sum, the precision associated with qualitatively estimating
21 negative leakage accurately may involve huge errors that could be so great as to overwhelm any
22 usefulness of the development of high quality data for other interrelated parts of the assessment.
23 If the magnitude of leakage cannot be calculated, however, its direction should at least be stated
24 and incorporated in some fashion. A default assumption that leakage is zero is neither helpful
25 nor accurate.

26
27 Thus, on balance, the *Framework*, while including many important elements suffers from
28 significant estimation and implementation problems. Some of these implementation issues with
29 estimating BAF and leakage that will be discussed further in response to charge question 4.

30 31 **3.2. Does SAB support EPA’s distinction between policy and technical considerations** 32 **concerning the treatment of specific factors in an accounting approach?**

33
34 A clear line cannot be drawn between policy and technical considerations. There is insufficient
35 information given on EPA’s policy context and menu of options to fully evaluate the
36 *Framework*. Because the reasonableness of any accounting system depends on the regulatory
37 context to which it is applied the *Framework* should describe the Clean Air Act motivation for
38 this proposed accounting system, how it regulates point sources for greenhouse gases and other
39 pollutants, making explicit the full gamut of Clean Air Act policy options for how greenhouses
40 gases could be regulated, including any potential implementation of carbon offsets or
41 certification of sustainable forestry practices, as well as its legal boundaries regarding upstream
42 and downstream emissions. Technical considerations can influence the feasibility of
43 implementing a policy just as policy options can influence the technical discussion. The two
44 need to go hand in hand rather than be treated as separable.

1 The *Framework* explicitly states that it was developed for the policy context where it has been
2 determined that a stationary source emitting biogenic CO₂ requires a means for “adjusting” its
3 total onsite biogenic emissions estimate on the basis of information about growth of the
4 feedstock and/or avoidance of biogenic emissions and more generally the carbon cycle.
5 However, in the discussion on the treatment of specific factors it states in several places that this
6 treatment could depend on the program or policy requirements and objectives. Certain open
7 questions described as “policy” decisions (e.g. the selection of regional boundaries, marginal
8 versus average accounting, inclusion of working or non-working lands, inclusion of leakage)
9 made the evaluation of the *Framework* difficult. Clearly, the policy context matters and EPA’s
10 reticence in describing the policy context and in taking positions on open questions (as well as
11 lack of implementation details) meant that the *Framework* was inadequately defined for proper
12 review and evaluation.

13
14 Specifically, if the policy context is changed, for example, if carbon accounting is needed to
15 support a carbon cap and trade or carbon tax policy, then the appropriateness of the *Framework*
16 needs to be evaluated relative to alternative approaches such as life cycle analysis for different
17 fuel streams. Modifying how certain factors are measured or included may not be sufficient. In
18 fact, a different *Framework* would probably make sense if a national or international greenhouse
19 gas reduction commitment exists. Furthermore, the BAFs developed for regulating the emissions
20 from stationary sources would likely conflict with measures of greenhouse gas emissions from
21 bioenergy used in other regulations such as California’s cap and trade system for regulating
22 greenhouse gases.

23
24 In a perfect world with full information and unlimited policy choices, carbon limits (or prices)
25 would be implemented economy-wide and not selectively enacted for particular sources or
26 sectors. Economic research has shown that the most cost-effective way to reduce greenhouse gas
27 emissions (or any other pollution) is to regulate or tax across all sources until they face a
28 marginal cost of emissions reduction that equals the marginal benefit of emissions reduction and
29 is equal across sources. In our less perfect world with EPA’s limited authority under the Clean
30 Air Act, the most efficient economy-wide solution is not within EPA’s menu of policy choices.
31 EPA’s regulation of stationary sources will exclude other users of biomass that have equivalent
32 impacts on the carbon cycle as well as downstream emissions from consuming the products
33 produced by these facilities.

34
35 In this second-best world with limited policy instruments that can be applied only to limited
36 sources, it would be desirable for EPA to ascribe all changes in greenhouse gas emissions (both
37 upstream and downstream of the stationary source) caused by the operation of the stationary
38 source to that source. Ideally, these emissions would need to be determined on a facility-specific
39 basis but facility-specific calculations would require a chain of custody accounting and involve
40 other daunting challenges such as estimating leakage effects.

41
42 As will be discussed in Section 6.3, given the sub-optimal choices facing EPA, one hybrid
43 approach would be a categorical inclusion with opt-out provisions. Stationary sources would be
44 subject to a categorical inclusion unless they opted out by certifying that their biomass was
45 sustainably harvested and produced using best management practices. By making the stationary
46 source responsible for demonstrating “sustainability”, the source would be linked to its land base.

1 This would remove the perverse situation of a responsible bioenergy facility, using feedstock
2 produced in a highly sustainable manner, being penalized because it happens to be located in a
3 region where other, less sustainable forest activities are causing carbon stocks to decline. It
4 would also avoid the problem of a bioenergy facility that uses biomass harvested in an
5 unsustainable manner benefiting from operating in a region where carbon stocks happen to be
6 growing. This may, however, increase complexity and costs of accounting for the carbon
7 emissions of a stationary source and require the development of certification systems that can
8 certify that biomass used by a facility was harvested sustainably. Caution is also advised that
9 such an approach could create global leakage effects that may overwhelm any carbon reduction
10 achieved. The case could occur in which a facility using sustainably produced biomass has an
11 apparent benefit on a regional scale but net negative effects on a global scale. The SAB cannot
12 offer an opinion on the legal feasibility of a categorical inclusion with opt-out provisions based
13 on certified feedstocks but we commend it to the Agency's attention for consideration.

14
15 **3.3. Are there additional factors that EPA should include in its assessment? If so,**
16 **please specify those factors.**
17

18 As stated above, for agricultural biomass from energy crops and crop residues, the factors
19 included in the *Framework* capture most of the direct off-site adjustments needed to account for
20 the changes in carbon stocks caused by a facility using agricultural feedstocks although they do
21 not account for leakage. For forest biomass, the *Framework* needs to incorporate a) the time path
22 of carbon recovery in forests (after energy emissions from harvested roundwood) or b) the time
23 path of the “anyway” emissions that would have occurred on the land if logging residue were not
24 used for energy production. For municipal solid waste biomass, the *Framework* needs to
25 consider other gases and CH₄ emissions from landfills when municipal solid waste is used for
26 energy production. Given that methane emissions from landfills are often captured, crediting
27 waste material for avoided emissions of methane may be inappropriate. The carbon impact of
28 using waste for energy production should be measured relative to the CH₄ emissions, if any, that
29 would be released during decomposition in a landfill. Note that the *Framework* should account
30 for the fact that CH₄ emissions from landfills are sometimes captured already. N₂O emissions,
31 especially from fertilizer use, should also be considered. Furthermore, the inclusion of non-CO₂
32 greenhouse gases in general should be consistent between biogenic and fossil fuel accounting.
33 For instance, there are also transportation related emissions losses in the delivery of natural gas.

34
35 **3.4. Should any factors be modified or eliminated?**
36

37 For reasons discussed above, factors such as PRODC, AVOIDEMIT and SEQP need to be
38 modified to include the timescale over which carbon is decomposed or released back to the
39 atmosphere. LAR needs to be modified to be scale insensitive and to address additionality.
40 Factors can be separated by feedstocks according to their relevance for accounting for the carbon
41 emissions from using those feedstocks. For example, GROW and leakage may not be relevant
42 for crop and forest residues.

1 **Charge Question 4**
2

3 **4. Evaluation of Accounting Framework**
4

5 **EPA's *Accounting Framework* is intended to be broadly applicable to situations in which**
6 **there is a need to represent the changes in carbon stocks that occur offsite, beyond the**
7 **stationary source, or in other words, to develop a "biogenic accounting factor" (BAF) for**
8 **biogenic CO₂ emissions from stationary sources.**
9

10 **4.1. Does the *Framework* accurately represent the changes in carbon stocks that occur**
11 **offsite, beyond the stationary source (i.e., the BAF)?**
12

13 For agricultural biomass, the variables in EPA's proposed equation for BAF represent the basic
14 factors necessary for estimating the offsite carbon change associated with stationary source
15 biomass emissions, including changes in storage of carbon at the harvest site. For short recovery
16 feedstocks, where carbon recovery and "anyway" emissions are within one to a few years (i.e.,
17 agricultural residues, perennial herbaceous crops, mill wood wastes, other wastes), with some
18 adjustments and appropriate data, the *Framework* can accurately represent carbon changes
19 offsite. However, for long recovery feedstocks where carbon recovery and most "anyway"
20 emissions occur over decades (i.e., wood harvested specifically for energy use (roundwood) and
21 logging residue), the *Framework* does not accurately account for carbon stocks changes offsite
22 for several reasons discussed below in response to charge question 4.2.
23

24 The *Framework* also does not consider other greenhouse gases (e.g. N₂O from fertilizer use and
25 CH₄ emissions from landfills). Excluding CH₄ because it is not "CO₂" is not a legitimate
26 rationale. It would need to be included to estimate the "difference in CO₂ (equivalent)" the
27 atmosphere sees. In addition, excluding CH₄ from landfills is inconsistent with the *Framework's*
28 desire to account for displaced on-site changes in CO₂. For the same reasons, the basis for
29 excluding N₂O emissions is unclear. It also needs to be included to estimate the net changes in
30 atmospheric greenhouse gases. Accounting for N₂O from fertilization would be consistent with
31 tracking changes in soil carbon which are a response to agricultural management systems, which
32 includes fertilizer decisions.
33

34 **4.2. Is it scientifically rigorous?**
35

36 The SAB did not find the *Framework* to be scientifically rigorous. Specifically, we identified a
37 number of deficiencies that need to be addressed.
38

39 The following issues require additional scientific support.
40

41 *Timescale:* One deficiency in the EPA report is the lack of discussion and proper consideration
42 of the different timescales inherent in the carbon cycle and the climate system that are critical for
43 establishing an accounting system. This is a complicated subject because there are many
44 different timescales that are important for the issues associated with biogenic carbon emissions.
45

1 An important timescale for considering accounting systems for biogenic carbon emissions is the
2 period over which the climate responds to carbon dioxide and other greenhouse gases. Several
3 different climate modeling studies have demonstrated that peak warming in response to
4 greenhouse gas emissions is primarily sensitive to cumulative greenhouse gas emissions over a
5 period of roughly 100 years, and is relatively insensitive to the emissions pathway within that
6 time frame.¹ What this means is that an intervention in forests or farming that results in a change
7 in storage of carbon must endure for significantly longer than 100 years in order to have any real
8 influence on the peak climate response.

9
10 If a carbon stock is cycling quickly on land, turning over and being replaced fully in less than
11 100 years then it may be beneficial to use biogenic carbon to displace the combustion of fossil
12 fuel. If the carbon stock, or some part of it, turns over more slowly, i.e., much longer than 100
13 years, the timing of release begins to matter. Examples of the former are forest harvest and
14 regrowth, even including accelerated harvests, and energy crops. Examples of the latter are land
15 conversion to a significantly difference average carbon stock. The fundamental differences in
16 stocks and their turnover times as they relate to impact on the atmosphere is not well discussed
17 or linked into the current framework. Differences among feedstocks in their turnover times could
18 justify how different feedstocks need to be incorporated into the *Framework*. At the moment,
19 there is little background discussion of the variation in the stock and turnover and how that
20 informs the accounting method. A fuller discussion of timescale of turnover of biogenic carbon
21 stocks could inform the *Framework*, perhaps justifying the groupings of feedstocks based on
22 their carbon cycling and likely impact on the atmosphere; those that have little or no impact,
23 have partial impact, or can have significant impact.

24
25 Scientific understanding of the timescale over which the climate system responds to cumulative
26 emissions implies that the carbon release caused by harvesting and combusting biomass at
27 stationary sources is a serious problem if the time for regrowth is much more than 100 years.
28 This means that the climate system is not sensitive to the imbalance in the carbon cycle that
29 might occur over decades from harvesting of biomass for bioenergy facilities. A scientifically
30 rigorous evaluation of the biomass harvest on the carbon cycle must consider the temporal
31 characteristics of the cycling. Annual accounting of carbon stocks is likely to give highly
32 distorted assessments of the overall carbon cycle impacts.

33
34 The *Framework* also does not consider the length of time it takes ecosystems to respond to
35 disturbances, such as those due to the harvesting of biomass, nor does it consider the spatial
36 heterogeneity in this response. This has implications for the accuracy with which the impact of
37 different land management strategies on carbon stocks in soil and vegetation is estimated.

38
39 The *Accounting Framework* subtracts the emissions associated with products, including ethanol,
40 paper, and timber, from the calculation of emissions from a stationary source, through the
41 PRODC term. While EPA may not have the discretion to treat all emissions equally,
42 distinguishing between immediate emissions from the facility and downstream emissions (as

¹ Allen, M. R., D. J. Frame, C. Huntingford, C. D. Jones, J. A. Lowe, M. Meinshausen and N. Meinshausen. (2009). "Warming caused by cumulative carbon emissions towards the trillionth tonne." *Nature* **458**(7242): 1163-1166. Allen et al. (2009)

1 these products will inevitably be consumed within a short period of time) does not make sense
2 scientifically. From the perspective of the carbon cycle and the climate system, there is no
3 difference between these two types of emissions. All these facilities extract biomass from the
4 land, and the vast majority of that biomass is converted to carbon dioxide, adding to cumulative
5 emissions and, hence, a climate response.

6
7 *Spatial scale:* There is no peer reviewed literature cited to support the delineation of spatial
8 scales for biogenic CO₂ accounting. In addition, the *Accounting Framework* allows different
9 carbon pools to be accounted for at different spatial scales with little justification. The
10 atmospheric impact of feedstocks is gauged on a regional basis in terms of its impact on forest
11 carbon stocks (except for case study 5). On the other hand, impacts due to land use change or
12 removal of residues such as corn stover (as captured in the SITE-TNC variable) which impact
13 soil C pools are accounted for using site specific accounting.

14
15 The *Accounting Framework's* use of a regional scale for accounting for the net changes to the
16 atmosphere is an artificial construct developed to (a) avoid the need for site-specific chain of
17 custody carbon accounting with separate streams for each feedstock and (b) as an alternative to
18 capturing changes in carbon stocks over time. The calculation of LAR captures landscape wide
19 changes rather than facility-specific carbon emissions associated with actual fuelsheds. Thus, the
20 *Accounting Framework* captures changes over space, in a sense, substituting space for time.
21 This approach attempts to simplify implementation using available forest inventory data and
22 avoids the need for accounting for changes in carbon stocks specific to the site or feedstock
23 sourcing region (fuelshed) which may be more complex and costly and difficult to verify.
24 However, it makes the estimate of the BAFs sensitive to the choice of the spatial region chosen
25 for accounting purposes. There is no peer reviewed literature to support a decision about the
26 appropriate spatial scale for determining LAR, and as shown by case study #1, there are
27 significant implications of this choice for the emissions attributed to the facility. Specifically, a
28 ton of carbon emitted in one part of the country may be treated differently from a ton of carbon
29 emitted elsewhere.

30
31 *Additionality:* A key question is whether the harvesting of biomass for bioenergy facilities is
32 having a negative impact on the carbon cycle relative to emissions that would have occurred in
33 the absence of biomass usage. This requires determining what would have happened anyway
34 without the harvesting and comparing the impact with the harvesting of biomass for a bioenergy
35 facility in order to isolate the incremental or additional impact of the bioenergy facility.
36 However, while the *Framework* discusses the “business as usual” or “anticipated future baseline”
37 approach, it implements a reference point approach that assesses carbon stocks on a regional
38 basis at a given point in time relative to a historic reference carbon stock.

39
40 For forest carbon stocks, the choice of a fixed reference point may be the simplest to execute, but
41 it does not actually address the question of the extent to which forest stocks would have been
42 growing/declining over time in the absence of this bioenergy facility. The use of a fixed
43 reference point baseline implies that forest biomass emissions could be considered carbon neutral
44 if forest stocks are increasing. This is simply an artifact based on the choice of the baseline that
45 will be used. The problem is thus: a region with decreasing carbon stocks may in actuality have
46 more carbon than what would have happened without the facility using biomass. Similarly, a

1 region with increasing carbon stocks may have less than would have happened without the
2 facility using biomass. By default, this approach creates “sourcing” and “non-sourcing”
3 regions. Thus, a carbon accumulating region is a “source” of in situ carbon that can be given to
4 support biomass use, and a carbon losing region is a “non-source” of carbon and cannot support
5 biomass use. The reference year approach provides no assurances at all that a “source” region is
6 gaining carbon due to biomass use, or that a “non-source” region is losing carbon and will not
7 gain carbon due to biomass use.

8
9 For example, for roundwood use, a region may have carbon accumulation with respect to the
10 reference year (and be assigned LAR=1 according to the *Framework*); however, harvest of a
11 150+ year old forest in the region for energy production would be regarded as a carbon stock
12 gain even though there is less carbon than there would have been otherwise and we would
13 recover only a portion of its carbon within the next 100 years. Likewise, a region which has a
14 slight overall annual loss of carbon (LAR=0), could actually provide roundwood from light
15 thinning of a mid-aged forest, yielding greater regional carbon than there would have been
16 otherwise, where most of the carbon would recover within 100 years. The *Framework*, however,
17 would view the roundwood supply as carbon stock loss. Since we want to estimate the
18 “difference in atmospheric greenhouse gases” over some period we must estimate how carbon
19 recovery differs between a biomass use case and a case without biomass use (business as usual
20 case).

21
22 *Substitution of Space for Time in Measuring Carbon Stock Changes:* The *Framework* uses a
23 single year’s carbon accumulation – for an entire region – to compute the BAF offset for the
24 current annual biomass combustion emissions. This approach is based in part on the idea that we
25 can estimate carbon recovery over many years from current year harvest using information from
26 one year of carbon accumulation over a wide area (a region). However the BAF is sensitive to
27 the chosen size and composition of the region, particularly if the reference point baseline is used.

28
29 *Assessing uncertainty:* The *Framework* acknowledges uncertainty but does not discuss how it
30 will be characterized and incorporated to assess the potential uncertainty in the estimate of the
31 “carbon outcome” and the BAF value. There are numerous drivers that can change biogenic
32 carbon stocks, even in the absence of biomass harvesting for energy. These include changes in
33 economic conditions, domestic and international policy and trade decisions, commodity prices,
34 and climate change impact. There is considerable uncertainty about the patterns of future land
35 use, for example, whether land cleared for bioenergy production will stay in production for
36 decades to come. The potential impact of these forces on biogenic carbon stocks and the
37 uncertainty of accounting needs to be considered further. Ideally, EPA should put their BAF
38 estimates into context by characterizing the uncertainties associated with BAF calculations and
39 estimating uncertainty ranges. This information can be used to give an indication of the
40 likelihood that the BAFs will achieve the stated objective. The uncertainty within and among
41 variables for any estimate may vary widely between feedstocks and across regions. If a regional
42 BAF is to be used, and there is not scientifically justifiable reason for doing so, at the very least,
43 the uncertainty evaluation should be able to assess if an assigned BAF value for one feedstock in
44 one area can be confirmed to be significantly different than a BAF estimated and assigned in
45 another case. If there is no significant difference then they should be assigned one common
46 value. In addition, uncertainty information would allow policy makers to assign BAF values

1 after deciding on their aversion to the risk of assigning values that are too high or too low.
2 Characterizing the uncertainty and risks is a scientific question. Selecting an acceptable risk level
3 is a policy decision.
4

5 *Leakage:* The *Framework* states that the likelihood of leakage and the inclusion of a leakage
6 term will be based on a qualitative decision. There is essentially no science in the document
7 about how leakage might be quantified and no examination of the literature regarding non-
8 hypothetical leakage scenarios (consider Murray et al 2004). Any discussion/decisions regarding
9 a leakage term should be based on quantitative assessment and science. A number of
10 statements/assumptions were made regarding the area and intensity of wood harvest increases to
11 accommodate biomass access. There was no examination of the scientific literature on wood
12 markets and therefore no science-based justification for these statements/assumptions.
13

14 *Other areas:* Other areas that require more scientific justification include assumptions regarding
15 biomass losses during transport and their carbon implications, the choice of a 5 year time horizon
16 instead of one that considered carbon cyclind, and the decision to include only CO₂ emissions
17 and exclude other greenhouse gas emissions need more science based justification. Additionally,
18 assumptions about the impacts of forest harvests on soil carbon and land use changes on carbon
19 sequestration need to be more rigorously supported.
20

21 *Inconsistencies:* We found a number of inconsistencies within the proposed framework that
22 should be resolved or justified:
23

24 (1) Adjustments for fossil fuel emissions: Fossil fuel CO₂ emissions from stationary sources
25 under the Clean Air Act are currently not adjusted for offsite greenhouse gas emissions or
26 carbon stock changes. Does that imply that by default BAFs should be zero as well? No,
27 because, unlike fossil fuels, biogenic feedstocks have carbon sequestration that occurs
28 within a timeframe relevant for offsetting CO₂ emissions from the biomass' combustion.
29 There are also relevant non-CO₂ greenhouse gas emissions associated with biogenic
30 energy feedstocks (discussed below). What about greenhouse gas emissions generated
31 during fossil fuel and biomass feedstock production and transport? It is practical to be
32 consistent in the handling of these greenhouse gas emissions within the *Framework*—
33 either excluding or including them for both fossil and biomass feedstocks. Including them
34 would imply the need for a lifecycle analysis for both.
35

36 (2) Biogenic and fossil fuel emissions accounting for losses: The *Framework's* handling of
37 carbon losses during handling, transport, and storage introduces an inconsistency between
38 how fossil emissions are counted at a stationary source and how biomass emissions are
39 counted. For biomass emissions the *Framework* includes emissions associated with loss
40 of feedstock between the land and the stationary source. For natural gas the emissions
41 attributed to the stationary source do not include fugitive greenhouse gas emissions from
42 gas pipelines. Why would loss emissions be included for biomass when they are not
43 included for natural gas?
44

45 (3) Inconsistency in the consideration of land management and the associated greenhouse gas
46 flux accounting: The *Framework* accounts for soil carbon stock changes, which are a

1 function of land management system, soil, and climatic conditions. However, it does
2 account for the non-CO₂ greenhouse gas changes that are jointly produced with the soil
3 carbon changes, as well as influence both the below and above ground carbon stock
4 changes associated with the land management system.
5

- 6 (4) Reference year and BAU baseline use: The *Framework* proposes using a reference year
7 approach: however, it implicitly assumes projected behavior in the proposed approach for
8 accounting for soil carbon changes and municipal waste decomposition.

9
10
11 **4.3. Does it utilize existing data sources?**
12

13 First, and most importantly, the *Framework* does not provide implementation specifics.
14 Therefore, it is difficult to assess data availability and use. These issues are discussed here and in
15 Section 4.4 and 4.5 that follow.
16

17 A more meaningful question is “Are the proposed data sets adequate to account for the effects of
18 biogenic carbon cycling on CO₂ emissions from a facility?” The *Framework* does use existing
19 data, but the data are not adequate to attribute emissions to a facility. For example, the
20 *Framework* mentions the use of the USDA Forest Service’s Forest Inventory and Analysis (FIA)
21 data at some unspecified scale. However, carbon stock change data are likely not very accurate
22 at the scale of the agricultural or forest feedstock source area for a facility.
23

24 The *Framework* requires data and/or modeling of land management activities and their effects on
25 CO₂ emissions and stock changes. For example for agricultural systems, data are required on the
26 type of tillage and the effect of such tillage on soil carbon stocks for different soil types and
27 climatic conditions. Such data are not likely to be available at the required scales. For example,
28 in one of the case studies, the Century model is used to model soil C stocks. Is the use of this
29 particular model proposed as a general approach to implement the *Framework*? Since this model
30 generally addresses soil carbon only to a depth of 20 centimeters, does that represent a boundary
31 for the *Framework*? Recent work has shown that such incomplete sampling can grossly
32 misestimate changes in soil carbon for agricultural practices such as conservation tillage (Baker
33 *et al.*, 2007; Kravchenko and Robertson, 2011). Which version of the model? Would EPA run
34 this model, and select parameters appropriate for each feedstock production area for each
35 facility? How robust are the predictions of this model for the range of soils, climatic conditions,
36 and management practices expected to be covered by the *Framework*? Could some other model
37 be used that produces different results for a given facility?
38

39 The *Framework* implies that data are required from individual feedstock producers. Collecting
40 such data would be costly and burdensome. Additionally, to the extent that feedstocks are part of
41 commodity production and distribution systems that mix material from many sources, it is not
42 likely to be feasible to determine the source of all feedstock materials for a facility.
43

44 The *Framework* includes a term for leakage but eschews the need to provide any methodology
45 for its quantification. Mysteriously, example calculations are carried out for leakage in one of

1 the case studies. However, leakage can be positive or negative, and while many publications
2 speculate about certain types of leakage, no data are presented, nor are data sources for different
3 types of leakage discussed and suggested. The *Framework* does provide an example calculation
4 of leakage in the footnote to a case study, but this does not a substitute for a legitimate discussion
5 of the literature and justification and discussion of implications of choices. In addition, such data
6 are unlikely to be available at the scales required. The implications and uncertainties caused by
7 using some indicator or proxy to estimate leakage need to be discussed. If leakage cannot be
8 estimated well is it possible to put an error range on the leakage value (e.g., a uniform
9 distribution) and assess the impact of this uncertainty on the overall uncertainty in the BAF
10 value? For some cases, such as the conversion of agricultural land to biomass production from
11 perennial crops, leakage may be described as likely increasing net emissions. In cases such as
12 this where prior research has indicated directionality, if not magnitude, usch information should
13 be used. As previously noted, there is also a consistency issue with the reference year approach
14 because leakage estimates implicitly assume an anticipated baseline approach of some sort.

15
16 In summary, it is not clear that all of the data requirements of the *Framework* can be met.
17 Furthermore, even if the data are acquired, they may not be adequate to attribute emissions to a
18 facility.

19 20 **4.4. Is it easily updated as new data become available?**

21
22 The details of implementing the *Framework* are not clear, as discussed for other sub-questions.
23 Thus it is also not clear how feasible it would be to update the calculations. However, if many of
24 the data requirements cannot be met currently, as stated above, it is very likely that many of the
25 data will not be easy to update.

26
27 In principal it would be feasible to update the calculations as new data become available. Some
28 kinds of data, such as those from FIA are updated periodically, thus it would be feasible to
29 update the analysis. However, as discussed for other sub-questions, it is not clear exactly what
30 data and resolution are required and whether all the required data are readily available.

31
32 An annual or five-year time frame is suggested for updating calculations. For some kinds of data,
33 such as soil and forest carbon stocks, these time frames are too short to detect significant changes
34 based on current or feasible data collection methodologies; implying that statistical or process
35 models would be used to estimate short-term changes for reporting purposes.

36
37 Lastly, if BAF is not under the control of the facility, it would introduce considerable uncertainty
38 for the facility if the BAF were recalculated frequently. If the goal of a policy using this
39 framework was to reduce greenhouse gas emissions, an overly costly or burdensome accounting
40 framework might not achieve that goal.

41
42 However, if the accounting is infrequent, shifts in the net greenhouse gas impact may not be
43 captured.

44 45 **4.5. Is it simple to implement and understand?**

46

1 It is neither. While the approach of making deductions from the actual emissions to account for
2 biologically-based uptake/recovery is conceptually sound, it is not intuitive to understand
3 because it involves tracking emissions from the stationary source backwards to the land that
4 provides the feedstock rather than tracking the disposition of carbon from the feedstock and land
5 forwards to combustion and products. The *Framework* also appears to be difficult to implement,
6 and possibly unworkable, especially due to the requirements for the many kinds of data required
7 to make calculations for individual facilities. Additionally, the categories (variable names) in the
8 *Framework* do not match those used in the scientific literature and are therefore not intuitive.
9 Lastly, many elements of the *Framework* are implicit rather than explicit. For example, we
10 assume that there should be a time frame during which changes in atmospheric greenhouse gases
11 will be assessed, but this time frame is not explicit. The time frame for specific processes is often
12 implicit, such as the emissions of CO₂ from biomass that is lost in transit from the production
13 area to the facility; this loss is assumed to be instantaneous.

14
15 Much more detailed information is required about how the *Framework* would be implemented.
16 For example, the specific data sources and/or models to be used and frequency of updating
17 calculations and crediting as discussed under other sub-questions. To assess the adequacy of
18 data, more information is needed on implementation and the degree of uncertainty acceptable for
19 policymakers to assign BAF values.

20 21 **4.6. Can the SAB recommend improvements to the framework to address the issue of** 22 **attribution of changes in land-based carbon stocks?** 23

24 As mentioned in response to Charge Question 4.2, the *Framework* uses a reference year baseline
25 approach to determining BAF. In the case of long recovery feedstocks such as the use of wood
26 biomass for energy, this makes the estimation of LAR scale specific and prevents the
27 determination of any incremental or additional impact of the bioenergy facility on emissions. An
28 alternative approach to gauge the difference in greenhouse gas emissions associated with the use
29 of forest-derived woody biomass would be to adopt the anticipated baseline approach of
30 estimating a “business as usual” trajectory of emissions and comparing it with a trajectory that
31 incorporates bioenergy. The anticipated baseline approach should be applied to determine
32 changes in forest stocks due to the use of forest material for bioenergy as well as to determine the
33 changes in land use and soil carbon for all types of feedstocks.

34
35 In developing this anticipated baseline for forest materials, it is important to distinguish between
36 three broad categories of wood biomass for energy: (a) logging residues from roundwood
37 harvested solely for timber or pulp, (b) roundwood harvested solely for bioenergy and (c)
38 mixtures of logging residues (a) and roundwood (b) where it is difficult to distinguish between
39 logging residue and pulpwood harvested for energy. Sathre (2011) argues that as long as wood
40 biomass for fuel has low value relative to other products it is unlikely that forest sites will be
41 harvested solely for fuel. Wood being removed for fuel from these operations can be considered
42 logging residue for estimating BAF. However, it may be necessary to specify guidelines for
43 distinguishing logging residue from pulpwood harvested for bioenergy.

44
45 In the case of logging residues, it is arguably reasonable to assign them a BAF equal to zero
46 because they could be considered “anyway” emissions over a time period relevant for attaining

1 climate stabilization, e.g 100 or somewhat more years. More accuracy could be achieved by
2 projecting the emissions from decay of those residues over time and comparing that to the
3 biomass use case in which those residues are used for energy generation. For temperate climates,
4 emissions from logging residue can be over 80% to near 100% within 100 years (Schlamadinger
5 et al. 1995) (Palosuo et al. 2001). Factors that determine the extent of decay of logging residue
6 (emissions versus C addition to soil) and the rate of decay include temperature, precipitation and
7 type of decay fungi. Decay in very dry conditions is very slow, particularly for large logs.
8 Conifers in the west tend to be decayed by brown rot fungi which do not break down lignin
9 (about one-third of wood carbon). Hardwoods tend to be decayed by white rot fungi which break
10 down all wood including lignin. (Jessie Glazer, personal communication). Forest Service FIA
11 plot re-measurement data on dead and down wood for the East is currently being analyzed to
12 estimate rates of wood decay and may help in estimating logging residue decay.
13

14 In the case of roundwood harvested solely for bioenergy, it is more important to incorporate the
15 temporal dimension since their emissions remain in the atmosphere for some time before being
16 captured by biomass regrowth. The anticipated baseline would be a projection of forest
17 emissions in the absence of an increment in roundwood use for bioenergy while accounting for
18 both natural and human disturbances in forests. This would require making assumptions about
19 average growth rates, natural disturbances and landowner behavior. Integrated forest sector
20 models such as the Forest Service RPA Forest Sector models or FASOM could be used to project
21 cases with and without increased roundwood use for energy. This type of analysis would
22 estimate both direct emissions from wood energy use and well as direct land carbon change (on
23 land providing biomass) and indirect land carbon change (a form of negative leakage). U.S.
24 forest and agricultural land carbon change could be estimated by models such as FASOM and
25 the Forest Service RPA models include effects of changes in forest management intensity and
26 forest land area. Indirect land use changes outside the US would require a using a global model.
27 There would be many sources of uncertainty but alternate runs may be able to put boundaries on
28 this uncertainty. Historically revenue provided for wood from forests has resulted in substantial
29 investment to expand and increase forest growth and, based on this record, is an effect contained
30 in projections by numerous forest sector models.
31

32 In the case of long recovery feedstocks, Cherubini (2011) provides a method to estimate the
33 global warming potential (GWP_{bio}) of biomass harvested from a forest of given age and regrown
34 to the same age. GWP_{bio} is the ratio of (a) cumulative radiative forcing (over a certain period)
35 associated with an initial emissions minus absorption by forest regrowth and oceans divided by
36 (b) cumulative radiative forcing of the initial emission alone with absorption by oceans). This
37 could be a metric for LAR. This estimate would be appropriate if one could reasonably assume
38 that the human caused disturbance of forest site will be limited after biomass harvest in the
39 biomass use case, and the age of the timber at the time of harvest is known. In addition the
40 estimate assumes for the BAU case that there would have been near term harvest for timber that
41 would have limited growth. The estimate would need to be adjusted to assess variations in this
42 assumption. Cherubini's method may be able to use FIA data on age of forest areas harvested to
43 estimate an average GWP_{bio} / LAR . In addition to using Cherubini's method, FIA data might be
44 used to see what recovery is made by actual FIA plots that have been harvested and remeasured.
45

1 One concern about the anticipated baseline approach is the uncertainty associated with a
2 projection given potential future changes in markets, policies, technologies, and biophysical
3 circumstances. Note that what is of interest here is the difference between two projections, i.e.
4 whether carbon emissions increase or decrease as a result of using feedstock X. To the extent
5 that each projection is driven by the same factors, the uncertainty of concern is only the
6 uncertainty reflected in the delta between two projections. Presumably this would be lower than
7 the uncertainty about a single projection. Unlike the reference year approach, the BAU baseline
8 approach can provide an actual estimate of greenhouse gas change. The reference year approach
9 does not even attempt to estimate changes, and will be prone to errors in either direction.

10
11 A general issue in being able to make LAR or BAF estimates for wood from forests is to identify
12 combinations of limited conditions or plausibly assumed conditions for the BAU case and the
13 biomass use case over time that allow a constrained estimate. Given a constrained estimate –
14 such as the Cherubini method – we can assess the effect of varying the assumptions on LAR or
15 BAF..

16 17 **4.7. Are there additional limitations of the accounting framework itself that should be** 18 **considered?**

19
20 A number of important limitations of the *Framework* are discussed below:

21
22 Framework ambiguity: Key *Framework* features were left unresolved, such as the selection of
23 regional boundaries (the methods for determining as well as implications), marginal versus
24 average accounting, inclusion of working or non-working lands in the region when measuring
25 changes in forest carbon stocks, inclusion/exclusion of leakage, and specific data sources for
26 implementation. As a result, the *Framework's* implementation remains ambiguous. The
27 ambiguity and uncertainty in the text regarding what are stable elements versus actual proposals
28 also clouded the evaluation. If EPA is entertaining alternatives and would like the SAB to
29 entertain alternatives, then the alternatives should be clearly articulated and the proposed
30 *Framework* and case studies should be presented with alternative formulations to illustrate the
31 implementation and implications of alternatives.

32
33 Feedstock groups: The proposal designates three feedstock groupings. However, it is not clear
34 what these mean for BAF calculations, if anything. The *Framework* does not incorporate the
35 groupings into the details of the methodology or the case studies. As a result, it is currently
36 impossible to evaluate their implications.

37
38 Potential for Unintended consequences: The proposed *Framework* is likely to create perverse
39 incentives for investors and land-owners and result in unintended consequences. For investors,
40 the regional baseline reference year approach will create regions that are one of two types —
41 either able to support bioenergy from forest roundwood (up to the gain in carbon stock relative to
42 the reference year), or not. As a result, a stationary source investor will only entertain keeping,
43 improving, and building facilities using biomass from regions designated as able to support
44 bioenergy. However, as noted previously, regions losing carbon relative to the reference year,
45 could actually gain carbon stock in relative terms due to improved biomass use and management
46 to meet market demands. In addition, the definitions of regions would need to change over time.

1 The designation of regions as able or not to support bioenergy that comes from the reference year
2 approach will create economic rents and therefore financial stakes in the determination of
3 regions and management of forests in those regions.

4
5 The proposed *Framework* could also potentially create perverse incentives for land-owners. For
6 instance, land owners may be inclined to clear forest land a year or more in advance of growing
7 and using energy crops. Similarly, land owners may be more inclined to use nitrogen fertilizers
8 on feedstocks or other lands in conjunction with biomass production. Such fertilization practices
9 have non-CO₂ greenhouse gas consequences (specifically N₂O emissions) that would not be
10 captured by the *Framework*. Agricultural intensification of production via fertilization is a
11 possible response to increased demand for biomass for energy.

12
13 *Assessment of Monitoring and Estimation Approaches:* The *Framework* is also missing a
14 scientific assessment of different monitoring/estimation approaches and their uncertainty. This is
15 a critical omission as it is essential to have a good understanding of the technical basis and
16 uncertainty underlying the use of existing data, models, and lookup tables. A review of
17 monitoring and verification for carbon emissions from different countries, both from fossil and
18 biogenic sources, was recently released by the National Research Council that may provide some
19 guidance.

21
22

1 **Charge Question 5**

2
3 **Case Studies**

4
5 **5. EPA presents a series of case studies in the Appendix of the report to demonstrate how**
6 **the accounting framework addresses a diverse set of circumstances in which stationary**
7 **sources emit biogenic CO₂ emissions. Three charge questions are proposed by EPA.**

8
9 **5.1. Does the SAB consider these case studies to be appropriate and realistic?**

10 **5.2. Does the EPA provide sufficient information to support how EPA has applied the**
11 **accounting framework in each case?**

12 **5.3. Are there alternative approaches or case studies that EPA should consider to**
13 **illustrate more effectively how the framework is applied to stationary sources?**

14
15 **Overall Comments**

16
17 In general, case studies are extremely valuable for informing the reader with examples of how
18 the *Framework* would apply for specific cases. While they illustrate the manner in which a BAF
19 is calculated, the data inputs are illustrative and may or may not be the appropriate values for an
20 actual biomass to energy project. Moreover, they are simplistic relative to the manner in which
21 biomass is converted to energy in the real world. For all case studies, there should be additional
22 definition of the contexts, examples of how the ‘data’ are collected or measured, and a discussion
23 of the impacts of data uncertainty. Overall, the case studies did not fully cover the relevant
24 variation in feedstocks, facilities, regions, etc. of potential BAFs that is required to evaluate the
25 methodology. From a clarity and ‘teaching’ point of view, it might be useful to start with a
26 specific forestry or agricultural feedstock example as the ‘base case’, and then add in the impacts
27 of the more detailed cases, e.g., additional losses, products, land use changes. This may be more
28 useful than a series of completely separate examples, each including different pieces of the
29 framework/equation.

30
31 **5.1 Does the SAB consider these case studies to be appropriate and realistic?**

32
33 The case studies did not incorporate “real-world” scenarios which would have served as models
34 for other situations that may involve biogenic carbon emissions. More would have been learned
35 about the proposed *Framework* by testing it in multiple, unique case studies with “real world”
36 data development and inclusion. The current set of case studies did not fully cover the relevant
37 variation in feedstocks, facilities, regions, etc. of potential BAFs that would be required to
38 evaluate the methodology. Among other things, additional case studies for landfills, switchgrass,
39 waste, and other regions are necessary, as well as illustrations of the implementation of feedstock
40 groups, and framework alternatives.

41
42 For example, Case Study 4 considers a scenario where corn stover is used for generating
43 electricity. While it is possible that this particular scenario could be implemented, for the present
44 time and maybe into the future, this particular case study does not mirror a “real world” case in
45 that very few if any electrical generation facilities would combust corn stover or agricultural crop
46 residues only. A more likely scenario might be a co-firing facility with a fossil fuel at low

1 percentages. Additionally, the assumptions made in this case about biomass yield and the rate of
2 growth of yield are not realistic. The yield of corn stover is expected to vary considerably across
3 the region expected to supply biomass to a facility and to grow over time and not be uniform as
4 assumed in the Framework.

5
6 In another example, Case Study 5 calculates the net biogenic emissions from converting
7 agricultural land in row crops to poplar for electricity production. This case study is also not
8 representative of “real world” agricultural conditions as switching from one energy crop to
9 another is not realistic. The formula provided for estimating the standing stock of carbon in the
10 aboveground biomass in the poplar system is not intuitive. The methods for determining biomass
11 yield as well as for measuring changes in soil carbon, which will depend on current use of the
12 land (whether it is conventionally tilled or under a perennial grass), are not described.

13 14 **5.2. Does the EPA provide sufficient information to support how EPA has applied the** 15 **accounting framework in each case?**

16
17 There remained considerable uncertainty in many of the inputs. In addition, some
18 sensitivity/uncertainty analysis would be useful. The results of this analysis may guide EPA in
19 further model development. For example, if the BAF is determined to be zero, or not statistically
20 different from zero in most case studies, then this could pave the way for a simpler framework.
21 As discussed in Section XS, a simpler framework based on categorization of feedstocks could be
22 designed to identify cases where biomass to energy generally results in a BAF of 0, 1 or
23 something in between.

24 25 **5.3. Are there alternative approaches or case studies that EPA should consider to** 26 **illustrate more effectively how the framework is applied to stationary sources?**

27
28 The major recommendation is additional case studies be performed and that these case studies be
29 designed to describe actual or proposed biomass to energy projects where the framework would
30 be used based on “real-world” situations of biomass development, production, and utilization.

31
32 For example, Case Study 1 describes the construction of one new plant. What would happen if
33 ten new plants were to be proposed for a region? In each case study, we would like to see
34 development of the required data and an assessment of whether data development can be
35 standardized and/or simplified. And how would the introduction of multiple facilities at the
36 same time impact the accounting for each facility? We support the suggestion in the report that
37 look-up tables be developed. However, only by trying to develop these look-up tables can EPA
38 assess whether this is workable.

39
40 All terms/values used to determine the BAF need to be referenced to actual conditions
41 throughout the growth/production/generation processes that would occur in each case study
42 including how these values would actually be implemented by one or more parties/entities
43 involved.

44
45 Examples of needed case studies could be perennial herbaceous energy crop, annual
46 energy/biomass sorghums, rotations with food and energy crops, cropping systems on different

1 land and soil types, municipal solid waste and internal reuse of process materials and
2 assessments across alternative regions that represent distinctly different types.

3
4 For example it would be very useful to consider the application of this framework to a cellulosic
5 ethanol plant fueled with coal or gas, and consider the emission of CO₂ from fermentation (not
6 combustion) and the production of ethanol which is rapidly combusted to CO₂ in a non-
7 stationary engine. There are three major sources of CO₂ emissions (list them here), but only one
8 is included in this framework, only two may be considered under the clean-air action, but all
9 three are emissions to the atmosphere. This lack of internal consistency makes the evaluation
10 difficult.

11
12 Among the case studies, we suggest that there be two on municipal solid waste. One case study
13 should be on waste combustion with electrical energy recovery. Here, as described in the report,
14 a BAF of zero is appropriate and this case study is quite simple. EPA should also perform a case
15 study on landfill disposal of municipal solid waste. Here it is important to recognize that
16 landfills are repositories of biogenic organic carbon in the form of lignocellulosic substrates
17 (e.g., paper made from mechanical pulp, yard waste, food waste). There is literature to
18 document carbon storage and EPA has recognized carbon storage in previous greenhouse gas
19 assessments of municipal solid waste management. There are potentially also avoided CH₄
20 decomposition emissions that need to be accounted for.

21
22 In Case Study 3 the data used in Table 3 to describe the ‘paper co-product’ will vary with the
23 grade of paper. The ‘carbon content of product’ may vary between 30% to 50% depending on
24 the grade and the amount of fillers and additives. Also, some significant carbon streams in a mill
25 can go to landfills and waste water treatment. The submitted comments from NCASI include a
26 useful example of the detail/clarity that could be used to enhance the value of the Case Studies.

27
28 After completion of the case studies, there should be a formal evaluation of (1) whether the
29 results make sense and achieve appropriate results with respect to biogenic CO₂ emissions (2) the
30 ease with which data were developed and the model implemented, and (3) whether the results are
31 robust and useful in recognition of the uncertainty in the various input parameters, and (4)
32 whether the model results lead to unintended consequences as discussed in response to charge
33 question 4.7.

34
35 Case studies could be developed to assess and develop a list of feedstocks or applications that
36 could be excluded from accounting requirements as anyway emissions. A sensitivity analysis
37 using case studies could be used to develop reasonable offset adjustment factors if they are
38 needed to adjust anyway feedstocks for impact on long term stocks like soil if needed.

1 **Charge Question 6**
2

3 **6. Overall, this report is the outcome of EPA’s analysis of the science and technical issues**
4 **associated with accounting for biogenic CO₂ emissions from stationary sources.**

- 5 • **Does the report – in total – contribute usefully to the advancement of understanding**
6 **on accounting for biogenic CO₂ emissions from stationary source?**
- 7 • **Does it provide a mechanism for stationary sources to adjust their total onsite**
8 **emissions on the basis of the carbon cycle?**
- 9 • **Does the SAB have advice regarding potential revisions to this draft study that**
10 **might enhance the utility of the final document?**

11
12 **6.1. Does the report-in total-contribute usefully to advancement of understanding of**
13 **accounting for biogenic CO₂ emissions from stationary sources?**
14

15 Yes, the *Framework* contributes to advancing understanding of accounting for biogenic
16 emissions and addresses many issues that arise in such an accounting system. It is thoughtful and
17 far reaching in the questions it tackles. Its main contribution is to force important questions and
18 offer some ways to deal with these. The report covers many of the complicated issues associated
19 with the accounting of biogenic CO₂ emissions from stationary sources and acknowledges that
20 choices made in the *Framework* to address them will have implications for the estimates of CO₂
21 emissions obtained. These include those raised by SAB and discussed above, related to the
22 choice of baseline, region selection and the averaging of emissions/stocks over space and time.
23 However, the solutions offered in many cases, particularly those related to the use of harvested
24 wood for bioenergy, lack a scientific justification.
25

26 **6.2. Does it provide a mechanism for stationary sources to adjust their total onsite**
27 **emissions on the basis of the carbon cycle?**
28

29 Clearly the *Framework* offers a mechanism to adjust total on-site emissions. For short recovery
30 feedstocks, where carbon recovery and “anyway” emissions are within one to a few years (i.e.,
31 agricultural residues, perennial herbaceous crops, mill wood wastes, other wastes), the
32 Framework could, with some modifications, accurately represent the direct carbon changes
33 offsite however leakage, both positive and negative, remains a troublesome matter if left
34 unresolved. However, the *Framework* offers no scientifically sound way to define a region for
35 measuring LAR for forest biomass. The definition of the regional scale can make a large
36 difference to the estimate of emissions from a facility using wood as a biomass. Moreover, if
37 there is no connection between actions of the point source and what happens in the region there
38 is no scientific foundation for using regional changes in carbon stocks to assign a BAF to the
39 source.
40

41 The *Framework* also does not make a clear scientific case for use of waste or what is called
42 “anyway” emissions. Scientifically speaking, all biogenic emissions are “anyway” emissions.
43 Even most woody biomass harvested from old growth forests, would, if left undisturbed
44 eventually die, decompose, returning carbon to the atmosphere. The appropriate distinction is
45 not whether the product is waste or will eventually end up in the atmosphere anyway, but

1 whether the stationary source is leading to an increase or a decrease in biogenic carbon stocks
2 and associated change in GWP. To do this, the *Framework* must consider the time period for
3 “anyway” emissions and that this may vary across different types of waste feedstocks.
4

5 An important limitation of the proposed *Framework* is that the accounting system
6 replaces space for time and applies responsibility to things that happen on the land, to a
7 point source, for which the agent who owns that point source has no direct control. The
8 proposed approach would estimate an individual point source’s BAF based on average
9 data in a region in which it is located. Any biogenic carbon accounting system that
10 attempts to create responsibility or give credit at a point source for carbon changes
11 upstream or downstream from the point source must relate those responsibilities and
12 credits to actions under control of the point source. However, the *Framework* does not
13 clearly specify a cause and effect relationship between a facility and the biogenic CO₂
14 emissions attributed to it. In particular, If the BAF is assigned to a plant when it is
15 approved for construction, as the BAF is currently designed, those emissions related to
16 land use change will have nothing to do with that actual effect of the point source on land
17 use emissions because the data on which it is based would predate the operation of the
18 plant.
19

20 The dynamics of carbon accumulation in vegetation and soils present a challenge for any
21 accounting system because in principle it implies that BAF estimates such as those proposed by
22 EPA should be based on anticipated future changes in vegetation. These future changes depend
23 on natural processes such as fires and pests that are not easily foreseen, and because of climate
24 change and broader environmental change we face a system that is certainly not stable, and so
25 projecting forward based on current or historical patterns is likely to generate significant errors
26 and biases of unknown direction and magnitude. More important, however, is that land use
27 decisions are under control of landowners, whose actions would need also to be projected. The
28 *Framework* recognizes this issue and chooses to use a Reference Point Baseline. The limitations
29 of this approach for adjusting the CO₂ emissions from biogenic sources have been discussed
30 above. As discussed in response to the next charge question, an alternative to using this approach
31 would be to develop an accounting system based on observable and measured changes rather
32 than projections as discussed in response to the charge question that follows.
33

34 EPA’s regulatory boundaries, and hence the *Framework*, are in conflict with a more
35 comprehensive carbon accounting that considers the entire carbon cycle and the possibility of
36 gains from trade between sources, among sources or between sources and sinks. For example,
37 by restricting its attention to the regulation of point source emissions, EPA’s analysis does not
38 allow for the possibility that a fossil CO₂ emitter could contract with land owners to offset their
39 emissions through forest protection and regrowth or carbon accumulation in soils. As far as the
40 climate is concerned, it makes no difference if land use change is used to offset CO₂ that was of
41 fossil origin or of biogenic origin, however, by staying within boundaries drawn narrowly around
42 the stationary source, the *Framework* eclipses a more comprehensive approach to greenhouse gas
43 reductions that would address all sources and sinks and take advantage of gains from trade.
44 Scientifically, a comprehensive carbon accounting would extend downstream—to emissions
45 from by-products, co-products, or products such as ethanol combustion or ethanol by-products

1 such as distillers dried grains (DDGs) that are sold as livestock feed and will soon become CO₂
2 (or CH₄).

3
4 **6.3. Does the SAB have any advice regarding potential revisions that might enhance the**
5 **final document?**

6
7 Overall, the *Framework* would be enhanced by including a description of the regulatory context
8 that has motivated the development of this framework and by specifying the boundaries for
9 regulating upstream and downstream emissions while implementing the regulation. The
10 motivation for the *Framework* should have been explained as it related to Massachusetts vs. EPA
11 (CITE), the Supreme Court ruling that found greenhouse gas emissions were subject to Clean Air
12 Act requirements if they were found to endanger public welfare and the environment. The
13 *Framework* should also make explicit the constraints within which greenhouse gases can be
14 regulated under the Clean Air Act. In doing this, EPA could be clear that these issues have not
15 been settled but that some assumptions were necessary to make a decision about the accounting
16 framework. EPA could also stipulate that further development of a regulatory structure might
17 require changes to the accounting system. While the SAB understands the EPA's interest in
18 describing an accounting system as a first step and potentially independent of the regulatory
19 structure, the reader needs this background in order to understand the context for the accounting
20 structure and to evaluate the scientific integrity of the approach.

21
22 Similarly, the *Framework* is mostly silent on how possible regulatory measures under the Clean
23 Air Act may relate to other policies that affect land use changes or the combustion/oxidation of
24 products from the point sources that will release carbon or other greenhouse gases. For example
25 if a regulatory or incentive system exists to provide credits for carbon offsets through land use
26 management then under some conditions it would be appropriate to assign a BAF of 1 to
27 biogenic emissions given that the carbon consequences were addressed through other policies.

28
29 The *Framework* does not describe how it will address emissions downstream from a point source
30 such as in the case of a biofuels or paper production facility where the product (biofuels, paper)
31 may lead to CO₂ emissions when the biofuels are combusted or the paper disposed of and
32 possibly incinerated. For example, if paper products are incinerated the incinerator may well be
33 a point source that comes under Clean Air Act regulation. However, biofuels used in vehicles
34 would not be subject to regulation as a point source. EPA needs to make clear the implicit
35 assumptions on how biogenic carbon will be treated upstream and downstream from the point
36 source if this *Framework* is used to regulate CO₂ emissions under the constraints imposed by the
37 Clean Air Act for regulating stationary sources.

38
39 *Recommendations for Revising BAF*

40
41 Overall, the SAB would prefer an alternative to the calculation of the BAF, given the daunting
42 technical and implementation challenges associated with implementing the *Framework*. If EPA
43 decides to revise the *Framework*, below we offer a summary of recommendations for specific
44 improvements in the calculation of BAF.

- 1 1. Develop a separate BAF equation for each feedstock category. Many of the issues raised
2 in previous responses regarding the treatment of specific factors included in the
3 *Framework* are specific to particular feedstocks. The clarity of the *Framework* would be
4 improved by differentiating among feedstocks based on how their management and use
5 interacts with the carbon cycle. Feedstocks could be categorized into short rotation
6 dedicated energy crops, crop residues, forest residues and long rotation trees. A BAF
7 equation should be developed for each of these categories of feedstocks, preferably
8 separating out “anyway” emissions feedstocks from those that have significant emissions.
9
 - 10 • Use an anticipated baseline approach for long recovery feedstocks like
11 roundwood, employing integrated forest sector models and/or Cherubini’s
12 GWP_{bio} .(as discussed in Section 4.6).
 - 13 • Develop an equation for municipal solid waste to take into account the
14 mix of biogenic waste with fossil fuel waste in combustion facilities as
15 well as the possibility of methane capture in landfills (as discussed in
16 Section 3.1).
- 17 2. Consider information about the directionality of leakage and leakage into other media (as
18 discussed in Section 3.1).
- 19 3. Omit the regional scale and incorporate a time dimension (as discussed in Sections 3.1,
20 4.2 and elsewhere). Certain factors in the BAF equation should be modified to include
21 the timescale over which carbon is decomposed or released back to the atmosphere. The
22 variable that represents the proportion of emissions that are offset by sequestration during
23 feedstock growth (LAR) needs to be modified to be scale insensitive and to address
24 additionality.
25
26
27

28 *Alternatives to BAF*

29
30 Given the conceptual deficiencies and prospective difficulties with implementation, the SAB
31 encourages EPA to “think outside the box” to search for an alternative to a categorical inclusion ,
32 exclusion or a facility-specific BAF. We offer the following three options for the Agency’s
33 consideration:
34

- 35 1. Develop a generic BAF for each feedstock category.
- 36 2. Consider certification systems.
- 37 3. Consider offset systems.

38
39 Option 1: Develop a generic BAF for each feedstock category. An alternative to revising the
40 *Framework* and calculating a BAF for each stationary facility is to develop general BAFs for
41 each category of feedstocks, differentiating among feedstocks using general information on how
42 their harvest and combustion interacts with the carbon cycle. Feedstocks could be categorized
43 into short rotation dedicated energy crops, crop residues, forest residues, long rotation trees and
44 waste materials. Special attention should be given by which feedstocks could be classified as
45 “anyway” emissions so that their BAF would automatically be either set to 0 or modeled as a

1 decay function. For longer recovery feedstocks, EPA would need to use forest growth models to
2 plot carbon paths that track regrowth following harvest or adopt a calculation of GWP_{bio} (as
3 discussed in Section 4.6). Many more case studies would be needed to develop an accounting
4 focused on feedstocks rather than the facility. These generic BAFs would be applied by
5 stationary facilities to determine their quantity of biogenic emissions that would be subject to
6 EPA's tailoring rule.

7
8 Option 2: Consider certification systems in a hybrid approach. This hybrid approach combined
9 a categorical inclusion with an opt-out provision whereby facilities could opt out by certifying
10 that their biomass was sustainably harvest and produced using best management practices. Such
11 "sustainability" would need to be certified by an authority using valid scientific measurements.
12 Requiring stationary facilities to use only "certified" feedstocks would be administratively
13 simpler than quantifying a specific net change in greenhouse gases associated with a particular
14 stationary facility. Certification approach can avoid the arbitrary scale issues and can perhaps
15 avoid or reduce leakage. By making the stationary source responsible for demonstrating
16 "sustainability", the source would be linked to its land base. This would remove the perverse
17 situation of a responsible bioenergy facility, using feedstock produced in a highly sustainable
18 manner, being penalized because it happens to be located in a region where other, less
19 sustainable forest activities are causing carbon stocks to decline. It would also avoid the problem
20 of a bioenergy facility that uses biomass harvested in an unsustainable manner benefitting from
21 operating in a region where carbon stocks happen to be growing.

22
23 Option 3: Consider offsets. The use of offsets could accompany either Option 1 or Option 2
24 above or even a calculated BAF for each facility (using the *Framework*). An offset system
25 would allow sources (e.g. a stationary energy producer) to contract with sinks (e.g. landowner) to
26 offset their emissions through forest protection and regrowth or carbon accumulation in soils.
27 Plants would need to meet a required BAF on an annual basis by acquiring carbon uptake credits
28 equal to their emissions. Since the atmosphere is indifferent between emissions reductions and
29 carbon accumulation, an offset need not be on a specific piece of land or even associated with the
30 specific point source. Offsets would need to be certified by an authority using valid scientific
31 measurements. Point sources could acquire certified storage credits, irrespective of their
32 relationship to the point source. For example, a landfill, a forest product producer, or biomass
33 waste energy generator could acquire credits for new production of lumber or paper products to
34 offset carbon in forest products that went through them or to offset land fill emissions or stack
35 emissions. Allowing flexibility in who could acquire these credits would encourage market
36 forces to seek these out. As firms compete to acquire certified carbon uptake or storage a market
37 will develop for these certified credits that will provide incentives for maintaining uptake/stocks
38 consistent with requirements for credits. Measurement and certification can be based on
39 observed carbon uptake or stock accumulation. These certifications can be over periods that
40 make sense and need not be made daily or annually. If concern exists that stocks of soil carbon
41 cannot be reliably estimated except over longer periods, then certifications may be limited to
42 period of 5 or 10 years. A certification system would also allow stationary source fossil emitters
43 to compete for biogenic credits.

44
